The reasons for racial–ethnic differences are not entirely understood. Poor socioeconomic conditions during childhood, as measured by household crowding and parental income, are thought to play an important role (see Section 5.5). US immigrant groups, for example, tend to have infection rates reflecting country of origin,[255,327,340] although it is not clear whether these differences are sustained over multiple generations after accounting for parents' infection, education, and household crowding.[236,327] Socioeconomic conditions cannot, however, completely explain observed differences and a genetic component cannot be entirely excluded.[273] A comparison of *H. pylori* concordance in monozygotic and dizygotic Swedish twins reared apart suggested that a proportion of infection may be attributable to genetic factors.[189]

5.5. Socioeconomic Status

Virtually all studies to date have shown an inverse relationship between *H. pylori* infection and socioeconomic status. A number of markers have been used as indirect measures of socioeconomic status including level of education, crowding, sharing of beds, and availability of indoor plumbing or hot running water in the home. In one large study (the EUROGAST serosurvey of 3,194 asymptomatic individuals in 17 countries), *H. pylori* seroprevalence showed a significant inverse association with educational level in 11 of the 17 population groups[66]; in the remaining 6 population groups, the inverse relationship remained but did not attain statistical significance. In Wales, age-adjusted prevalence of *H. pylori* was also found to be highest in the lowest social classes (62%), less in the middle class (57%), and lowest in the higher class (49%).[129]

Socioeconomic status during childhood may serve best as an indicator of *H. pylori* risk. For example, in 150 healthy African-Americans and Hispanics between the ages of 19 and 49 years, a combined index of parental education, occupation, and income was a strong predictor of *H. pylori* infection. About 85% of adults raised in the lowest socioeconomic stratum had infection compared to 11% in the highest stratum. The association remained after adjustment for age and current social class.[191] Studies of US high-income versus low-income families in Arkansas and in Texas support this finding.[76,109] In Japan, a country that has undergone dramatic economic development since the Second World War, 5,854 adults were asked to describe household living conditions before age 10 years. Lack of modern plumbing facilities and household crowding were significantly associated with contemporary *H. pylori* seroprevalence rates.[330] Studies from Korea and Mexico similarly link household hygiene in childhood with adult infection.[193,325] By contrast, infection rates among urban homeless adults in Toronto, Canada,[134] were similar to other Canadian adults[254] and not associated with common stomach complaints. These data reinforce incidence and prevalence data (Section 5.1) that point to unsanitary living conditions in childhood as a critical factor for acquiring infection.

6. Mechanisms and Routes of Transmission

Because acute infection invariably passes undetected (Section 8), acute *H. pylori* infection has rarely been diagnosed outside the experimental or iatrogenic setting. In the absence of such acute infections, particularly outbreak-related infections, the means of *H. pylori* transmission have had to be deduced using indirect epidemiologic methods. The majority of the resulting data support person-to-person transmission as the dominant, if not only, mode of transmission.

6.1. Person-to-Person Transmission

Epidemiologic studies of *H. pylori* transmission vary greatly in their design and implications. Many cross-sectional studies, comparing infection rates between groups with different risk factors, have been conducted. Seropositivity rates are higher than expected in close communities where hygiene is suboptimal, such as institutions for the disabled[20,32,149,169,272] and orphanages.[196,257] Infection rates also cluster within families, particularly if a child is the index case.[60,150,192,214,227] In population surveys, familial clustering is a particularly strong feature of community distribution, and this phenomenon has been observed worldwide, despite widely varying socioeconomic conditions.[143] In Belgium, investigators identified a 2.7-fold increased risk of *H. pylori* among first-degree family members of infected, symptomatic pediatric patients compared to the general population (48.6% compared to 17.8%).[29] In a Northern Italian community of 416 families, 44% of children with two infected parents were infected, compared with 30% with one infected parent and 21% with no infected parents.[59] Vietnamese children from 135 extended family homes were over twice as likely to be infected if the mother was infected and four times as likely if both parents were infected.[229] In Brazil, infection among preschoolers was associated with infection status of siblings as well as parents.[275] Other groups report similar results.[2,142,201,203,267,324,334] Patterns of familial risk have also been corroborated in some prospective studies. In a 9-year follow-up study in Japan, seroconversion was observed only among children of *H. pylori*-infected mothers.[195] In Benin, seroconversion of preschoolers was associated with having infected siblings as well as use of open water containers.[99] Outside of the family setting, attending day care[349] or school[323] with infected classmates does not appear to be associated with increased risk of infection. Military personnel deployed overseas under close field conditions may be at increased risk of developing infection in adulthood.[316]

Within households, infection rates have also been related to sibship size, birth order, and current number of children in the family, factors that serve as markers for increased risk of person-to-person transmission within households.[89,103,317] Crowding within households particularly engenders greater risk for infection. Bed-sharing among children, often associated with household transmission of enteric pathogens,[259] is an especially hazardous practice whether documented retrospectively[191,211,342] or concurrently.[72]

In DNA fingerprinting studies, strains of *H. pylori* are more likely to be similar within families than between unrelated individuals.[15,120,152,271] Strains are most closely related among siblings.[339] Among 39 families, 29 of 36 (82%) sibships had identical strains, compared with 10/18 (56%) mother–offspring and 0/17 (0%) father–offspring relationships.[152] In a small cohort series, 5/44 infants who developed infection in the first 5 years of life had strains identical to the mother[159]; however, neither sibling nor fathers' infection status was determined. Sibling strain concordance could represent recombination of a maternal strain, horizontal acquisition, or both.

Three mechanisms of person-to person spread are widely evaluated: fecal–oral, oral–oral, and gastro-oral (defined as iatrogenic transmission through introduction of infected instruments into the stomach) transmission. In favor of a fecal–oral route, one investigative team isolated *H. pylori* from feces of both children and adults, demonstrating that *H. pylori* can pass through the gastrointestinal tract and remain viable.[146,321] In another study using adult volunteers, cultivation was possible only from induced or catharctic, but not normal, stools.[248] In one household incidence study, exposure to gastroenteritis in an *H. pylori*-infected contact was associated with a 4-fold increase in risk of new infection, although exposure to diarrhea alone without vomiting could not be independently linked to new infection.[249] In addition, sewage workers do not appear to have excess risk compared to community controls.[86,140]

Patterns of *H. pylori* infection are perhaps more consistent with oral–oral transmission, particularly in the setting of vomiting or regurgitation. *H. pylori* is cultured reliably from vomitus.[36,177,248] In one comprehensive volunteer series, *H. pylori* (often in large numbers) was cultured from all 80 vomitus samples collected from 16 subjects, and also from a portion of aerosol samples obtained at distances up to 1.3 m, while diarrhea and saliva yields were substantially lower.[248] In the aforementioned household study, exposure to an *H. pylori*-infected household contact with vomiting resulted in a 6-fold increase in risk for new infection.[261] A higher incidence of *H. pylori* infection following outbreaks of gastroenteritis in an institution for the intellectually disabled[174] may consistently be oral–oral as well as fecal–oral transmission. Further support for oral–oral transmission in the setting of vomiting comes from a case–control study in which vomiting siblings and siblings of vomiting index children were 2.4 times more likely to be infected than children not exposed to vomiting.[185] In addition, two case reports—one involving two new infections following vomiting illness of an infected family member,[214] and a second following mouth-to-mouth resuscitation of a person with vomit in the mouth[77]—support this hypothesis.

In the absence of vomiting, it is unclear whether oral–oral transmission occurs. *H. pylori* DNA has frequently been recovered by PCR from both saliva and dental plaque.[162,199]

Only on a rare occasion, however, has *H. pylori* been actually cultured from the mouth.[74,162,248] If oral–oral spread is common, however, one would expect rates of infection among dental workers to be elevated compared to age-matched controls. This was not the case in one cross-sectional study.[190] In a small nested case–control study, Japanese dental professionals had an elevated, but non-significant, risk compared to controls.[207] There is also little concordance of infection among married couples in whom oral–oral transmission might be expected, by serology[258] or by PCR-restriction fragment length polymorphism analysis,[184,308] and treated spouses are not likely to be re-infected by an infected spouse.[49]

The only definitive mode of transmission is gastro-oral. Cases of *H. pylori* have been definitively linked by fingerprinting to transmission via endoscope,[172] and viable organisms can be cultured from gastric juice.[358] Also, outbreaks of *H. pylori*- associated hypochlorhydria have occurred with endoscopy and gastric pH testing in experimental subjects[106,240,270] (see Sections 6.3 and 8.1.1). Of course, this mechanism can explain only a small number of the billions of cases worldwide.

Thus, although the precise mechanism of transmission remains incompletely characterized, it is likely that *H. pylori* employs all three pathways to exploit the milieu of infectious gastroenteritis in close communities. As acute infection is associated with non-specific symptoms of vomiting and diarrhea,[111,138,249,261] it may promote itself during household transmission of common enteric pathogens, with young children serving both as sources and targets of new infection.[248,261] This might explain its persistence in human populations, why acquisition, including repeated acquisition, occurs primarily in early life, and why infection clusters so strongly within families.

6.2. Transmission from a Common Environmental Source

While the preponderance of evidence supports person-to-person spread of infection, some studies in developing countries have reported increased risk of infection in association with exposure to contaminated water,[132,142,154] food, or animals.[36,130] However, other studies are conflicting.[2,100] Numerous studies detecting *H. pylori* DNA in water samples or biofilms by PCR provide only circumstantial evidence of transmissibility.[341] While fecally contaminated water cannot be ruled out as a reservoir in developing countries, the organism has been cultured once under technically demanding conditions from contaminated water,[183] and never from natural water sources.[19] It remains unknown whether the coccoid form commonly observed when exposed to water is viable.[30] *H. pylori* has been isolated from monkeys,[61,82] cats,[121] and houseflies.[116] Conversely, some non-*H. pylori* helicobacters that colonize domestic animals are found in humans.[83] However, no evidence for a zoonotic route of transmission has been reported. Foods of animal origin also seem an unlikely source since vegetarians and meat eaters have similar rates of infection.[129,343]

6.3. Iatrogenic Transmission

Though rare, iatrogenic transmission via endoscopy has been well documented through the isolation of identical strains of *H. pylori* from patients undergoing endoscopy in the same suite. Transmission has been estimated to occur in 0.3% of endoscopies when the endoscope is mechanically cleaned with detergent and ethanol alone.[172] More rigorous cleansing methods, however, prevent transmission.[74,144,235]. Endoscopists and endoscopy nurses appear to be at particularly high risk for infection, leading some to call *H. pylori* an occupational hazard.[40,179] Observance of hospital infection control procedures, however, may mitigate this risk.[232]

7. Pathogenesis and Immunity

Because acquisition of *H. pylori* infection passes unrecognized, little is known about host and/or bacterial factors required for establishing infection. What is known derives largely from experimental or iatrogenic infection. Two self-infection studies are particularly illustrative. To prove the pathogenicity of *H. pylori*, in 1985, Barry Marshall neutralized his gastric pH with histamine blockers (first experiments without histamine blockers failed) and then ingested 10^9 *H. pylori* organisms. Gastroscopy with biopsy on day 10 confirmed infection and revealed antral gastritis. This gastritis resolved spontaneously by day 14. No antibody response developed. Arthur Morris repeated this self-experiment ingesting 3×10^5 *H. pylori*. Biopsies done on day 5 revealed severe inflammation of the antrum with normal fundus.[221] Fasting gastric pH was 1.2 at that time but had increased to 7.6 by day 8. An initial, transient IgM seroconversion was followed by subsequent development of both IgA and IgG antibody against *H. pylori*. Following a 4-week course of bismuth, biopsies revealed no organisms and resolution of inflammatory changes. Biopsy 1 year after ingestion, however, showed persistence of both *H. pylori* and chronic inflammation despite lack of symptoms.[223] The infection and pathological changes remained for over 3 years

until combination antimicrobial therapy successfully eradicated the infection.

These data, in conjunction with a study of experimental infections of volunteers (see Section 8.1), provide almost all that is known on incubation period (estimated 3–7 days).[111,203,221] They also support a hypothesis that there are "windows of opportunity" (such as periods of hypochlorhydria) when exposed persons are at increased risk for establishing infection. Given the high, but not universal, prevalence of *H. pylori* throughout the world, however, it seems likely that many are exposed who do not develop chronic infection.

Indeed, to cause infection, *H. pylori* must survive the highly acidic environment in the stomach and find a hospitable place to replicate. It does these tasks through prodigious production of the enzyme urease,[218] which surrounds the organism with an ammonia cloud, and by using its multiple flagellae to propel it into a protected niche within the mucus overlying the gastric epithelium.[65] Most organisms swim freely in the mucus layer but a minority adhere to the mucosal epithelium through a variety of microbial adhesins and epithelial receptors.[237] This adherence to gastric tissue appears to be highly specific and is related to features of both the host (e.g., blood group type) and the bacterium (e.g., strain).[33,181,335,336] Once established, *H. pylori* lives adjacent to gastric epithelium on the surface or in the mucous layer. Colonies are most commonly observed in the antrum, which lacks acid-secreting parietal cells, although it may also colonize the corpus. Infection is always accompanied by acute and chronic inflammatory changes in the gastric submucosa. The characteristic, histological lesion has been termed superficial active gastritis, type B gastritis, or, most recently, *H. pylori*-associated chronic gastritis with polymorphonuclear cell activity.[264] In the vast majority of infected patients, lymphoid follicles (mucosal-associated lymphoid tissue) also develop.[93] With rare exception, inflammation is accompanied by elevations in serum IgG against several *H. pylori* antigens including the urease subunits and, when expressed by the bacterium, the vacuolating cytotoxin and the CagA protein. *H. pylori* infection also elicits an IgA response in two thirds of infected persons.[161]

Inflammation is thought to be mediated by bacterial and host factors. Although all infected hosts show some degree of chronic and acute inflammation, the inflammatory responses are particularly pronounced in persons infected with strains that contain a cassette of genes named the Cag pathogenicity island (PAI).[263] A functional Cag PAI encodes a type IV secretion system that injects the CagA protein into epithelial cells causing tyrosine phosphorylation of a 145 kDa protein, cytoskeletal changes, breakdown of the epithelial gap junctions, and induction of epithelial cytokines.[224] A functional vacuolating cytotoxin (VacA) further augments the inflammatory response by inducing apoptotic cell death.[91] Inflammation also depends on the host's alleles of specific inflammatory cytokines, e.g., IL-1β, IL-10, and TNF-α.[266]

Although *H. pylori* elicits both a vigorous Th1 cell-mediated immune response in the gastric mucosa and IgG and IgA antibody responses,[307] there is no known natural protective immunity. Reinfection rates are perhaps minimally lower than primary infection rates within the same populations.[243] Vaccines that use adjuvants to boost the natural immune response are being explored. However, even in animals, protective immunity remains poorly understood and neither completely prevents colonization nor mitigates gastric inflammation.[1]

H. pylori-related gastritis can progress to a variety of clinical diseases. The pathogenic mechanisms for the variable outcome of infection, i.e., asymptomatic, ulcer, or cancer, are largely unknown. Simplistically, there appears to be a dichotomy in host response that is distinguished by the location of infection within the stomach and the associated acid response.[294] Some hosts develop predominantly antral gastritis with normal to high acid output. Infection in these individuals may progress to gastric metaplasia in the duodenum and subsequently duodenal ulcer disease. Gastric metaplasia allows *H. pylori* colonization of the duodenal mucosa, where its mucinases and other exoproteins can weaken the mucous barrier in the duodenum, fostering development of ulcers.[27,105,313] Such progression may be enhanced by environmental factors such as smoking or use of nonsteroidal anti-inflammatory agents. In contrast, other hosts develop with multifocal atrophic gastritis involving corpus and antrum with low acid output.[294] Infection in these individuals may progress to intestinal metaplasia, gastric ulcer, and cancer. These dichotomous responses rarely overlap, i.e., those with duodenal ulcer disease appear to be protected from gastric malignancy.[296,298] It is highly plausible that this dichotomy is attributable to differences in host genetics. For example, variations in interleukin 1β and interleukin 1 receptor antagonist genes are associated with both gastric acid secretion and disease outcome.[266] In contrast, the different outcomes are unlikely to be explained by the infecting strain; in both arms of the dichotomy, strains with the PAI and a functional cytotoxin contribute to disease outcome.[33,45]

Research on *H. pylori* as a cause of gastric cancer is proving informative for understanding carcinogenesis more generally. Chronic inflammation secondary to infection has long been known to predispose to carcinomas at the inflamed site. Inflammation typically induces epithelial cell death and accelerates cell proliferation, critical factors in mutation.

Inflammation also induces oxidative bursts of free radicals that potentially can damage DNA. Both enhanced cell proliferation and free radical formation have been observed with *H. pylori*-associated gastritis.[51,186]. Experiments in a mouse model suggest that inflammation also results in recruitment of bone marrow-derived stem cells to the site of injury.[131] Intriguingly, it is now posited that these stem cells, rather than epithelial cells, may be the progenitors of the carcinomatous tissue.

Because of its rarity, less is known about the pathogenesis of *H. pylori*-associated gastric lymphoma than about carcinoma. It appears, however, that *H. pylori* induces T-cells to stimulate B cell proliferation. These B cells are also stimulated by autoantigens in the gastric mucosa that result from cross-reactivity with *H. pylori* antigens. Over time, the lymphoproliferative response can lead to an accumulation of mutations within the B cells. In the early stages of this process, this proliferation can be mitigated by *H. pylori* eradication and the tumor will regress. At later stages, however, accumulated mutations can induce cell growth that is no longer responsive to *H. pylori* eradication.[137]

8. Patterns of Host Response

In the absence of specific antimicrobial therapy designed to eradicate the organism, infection with *H. pylori* typically remains in the stomach for decades, disappearing only in a minority of infected hosts.[88] Genetic fingerprinting analyses demonstrate persistence of the specific strains colonizing the individual.[88,173] Repeated serological testing over time also demonstrates that, in nonelderly adults, the serum IgG titer remains constant in the absence of specific eradication therapy.[171,245] In older adults, however, *H. pylori* colonization and serologic response may diminish or disappear over time in association with increasingly abnormal gastric histopathology.[158] Although the majority of infected individuals are asymptomatic, a spectrum of syndromes and diseases, including dyspepsia, peptic ulcer disease, gastric adenocarcinoma, and lymphoma, have been attributed to *H. pylori* infection. Given the wide variety of outcomes, cofactors such as genetic predisposition, smoking, alcohol, and diet undoubtedly play important roles in determining infection outcome.

8.1. Clinical Spectrum of Disease

Despite histological evidence of inflammation, the majority of individuals infected with *H. pylori* are asymptomatic. For example, in one study, 74% of 57 *H. pylori*-positive healthy blood donors were asymptomatic, whereas 26% reported dyspepsia-like symptoms. These symptoms were similar to those of the *H. pylori*-negative individuals.[127] Despite the lack of a defined, organism-specific clinical syndrome, *H. pylori* is clearly a cause of important clinical diseases. Intriguingly, it has also been touted as potentially protective against other disease processes.

8.1.1. Acute Symptomatic Gastritis. What is known about acute symptoms of *H. pylori* comes largely from experimental infections. In his self-inoculation experiment, Barry Marshall was asymptomatic until day 7 when he developed epigastric discomfort, vomiting, and irritability.[203] Three days after ingesting 3×10^5 *H. pylori*, Arthur Morris developed severe epigastric pain, stomach cramping, nausea, vomiting, and insomnia. Mild abdominal discomfort persisted for approximately 11 days after which all symptoms resolved.[209] An *H. pylori* challenge study conducted in preparation for a vaccine trial has now bolstered the clinical observations of the two pioneering self-inoculations. Among 20 subjects given *H. pylori* after acid suppression, 18 developed infection. All of these developed mild to moderate gastrointestinal symptoms—most commonly dyspepsia and abdominal pain; vomiting occurred in two. Symptoms began in the first week and peaked in the second week.[111]

Acute *H. pylori* infection has also occurred in epidemic form.[98,270] Two endoscopic studies were marred by outbreaks of acute gastritis illness and hypochlorhydria. In the larger of the two studies,[270] an increase in pH was detected in the previously healthy volunteers approximately 1 week after undergoing the gastric secretion studies. This was accompanied by transient epigastric pain, nausea, and vomiting in half of the subjects; the remaining subjects stayed asymptomatic despite increases in gastric pH. Retrospective analysis of biopsy and serum specimens in both series suggested that *H. pylori* was the etiologic agent of these outbreaks.

With naturally acquired infection, much less is known about symptoms. In a study of 1,752 persons followed for new *H. pylori* infection, no distinct symptoms were recognized in 30 patients with newly acquired infection.[261] In a serological study of epidemiologists tested for *H. pylori* infection on two occasions spanning a mean of 8 years, chronically infected subjects had similar symptoms to uninfected subjects. Persons who seroconverted in the 8-year interval, however, had significantly higher rates of self-described upper gastrointestinal symptoms.

8.1.2. Non-ulcer Dyspepsia. The role of *H. pylori* infection in non-ulcer dyspepsia (NUD) remains controversial. Exploring the relationship is problematic because of the wide variety of symptoms that fall under this catch-all term. Differences in the selection of patients for studies and

the method of diagnosis of *H. pylori* infection make comparison between them difficult. Some studies have shown a greater prevalence of *H. pylori* infection in patients with NUD, while others have not. Moreover, while some longitudinal studies have shown symptomatic improvement in dyspeptic patients after eradication of *H. pylori*, the results are not uniform.[168] The seeming inconsistencies may reflect the lack of control groups standardized for other known risk factors for *H. pylori* infection.[310] A Cochrane review of 17 randomized, placebo-controlled trials, however, revealed a 10% risk reduction in non-ulcer dyspepsia with *H. pylori* eradication.[216] Overall, 14 patients required treatment to cure 1 case of non-ulcer dyspepsia. The authors of this review drew no definite conclusion about whether this "modest benefit" warranted screening and treatment but rather encouraged further study.

8.1.3. Peptic Ulcer Disease. *H. pylori* is an important cause of both duodenal and gastric ulcers (1994). Although "no acid, no ulcer" is still an accepted dogma in duodenal ulcer pathogenesis, *H. pylori* is similarly critical. In some studies, over 90% of persons with duodenal ulcer disease had concomitant *H. pylori* infection and the attributable proportion was >90%.[11] In countries where *H. pylori* prevalence is lower and NSAID use is higher, the percent of ulcers with associated *H. pylori* may be as low as 55%.[265] The best evidence for a causal association between *H. pylori* and ulcer disease comes from therapeutic trials. Persons treated with antibiotics in addition to acid inhibitory therapy have lower rates of ulcer relapse than persons treated with acid inhibitory therapy alone.[108,126] Moreover, if the antimicrobial agents used do not successfully eradicate *H. pylori* infection, there is no benefit over acid inhibition alone.

Only a minority (approximately 20%) of infected persons will develop duodenal ulcer within a 10 years of diagnosis.[293] Factors that determine infection outcome include bacterial characteristics, host characteristics, and the environment. Strains containing the Cag PAI[231] and the s1m1 allele of *vacA* have higher-than-average risk.[18] Also at higher risk are individuals with genotypes of the cytokines TNF-α and IL-1β that induce greater inflammatory responses. Environmental cofactors such as cigarette and alcohol use, use of NSAIDs, male gender, and blood group O and other hereditary factors have also been associated with magnified ulcer risk.[295]

8.1.4. Gastric Adenocarcinoma. It has been estimated that *H. pylori* infection may be responsible for 5.5% of all cancers worldwide.[241] In 1994, the World Health Organization (WHO) declared *H. pylori* infection to be an important cause of gastric adenocarcinoma.[135] Support for this declaration came from two types of data: studies of the natural history of gastric cancer and epidemiological studies of the association of *H. pylori* infection and cancer. Since gastric cancer usually occurs in the setting of chronic superficial gastritis, a relationship with *H. pylori* can be deduced. The most compelling data linking *H. pylori* infection with cancer, however, came from epidemiological investigations. Several types of studies have been done including studies paralleling the epidemiological features of *H. pylori* infection and gastric cancer, case–control studies of patients with cancer, and nested case–control studies within large cohort populations followed, prospectively, for cancer. These studies show that (1) gastric cancer occurs at an increased rate in regions with high prevalence of *H. pylori* infection, (2) cancer patients have higher rates of *H. pylori* infection than controls, and (3) *H. pylori* infection precedes cancer by many years (1993).[230,246] In a large prospective study conducted in Japan, no uninfected persons developed cancer within 8 years, whereas 2.9% of infected hosts did.[331]

Although non-randomized, prospective studies demonstrate cancer protection with *H. pylori* eradication,[112,309] definitive randomized trials are still lacking. The single randomized, placebo-controlled trial completed to date showed decreased cancer incidence following *H. pylori* eradication only in the small subgroup of individuals without preneoplastic conditions; in the total population treated, significant protection in the 7 years following *H. pylori* eradication was not observed.[350] Because of the relatively short follow-up and smallish sample size in this study, further trials are warranted. Despite the absence of conclusive data, many investigators maintain that—based on the wealth of information collected to date—*H. pylori eradication* will ultimately prove effective in preventing the majority of gastric adenocarcinomas.

As with ulcer disease, gastric adenocarcinoma only occurs in a small minority of infected subjects. Again, bacterial factors (e.g., the presence of the pathogenicity island), host factors (e.g., cytokine genotype), and diet (low antioxidants, high salt and nitrate) play a contributing role.

8.1.5. Gastric Lymphoma. Gastric lymphoma is the rarest of the diseases associated with *H. pylori* infection, with only seven cases per million population per year.[289] The normal stomach is not a lymphoid organ. Since *H. pylori* is the preeminent initiator of inflammation and lymphoid follicle formation in the stomach, it seems intuitive that it would be linked to lymphoma. Several cross-sectional and ecological studies have weakly supported this conjecture.[58,81] One somewhat stronger study demonstrated that *H. pylori* infection increased risk of later developing diffuse histiocytic gastric lymphomas 6-fold.[247] A particularly strong association of infection has been observed for mucosa-associated lymphoid tissue (MALT) lymphoma, a type of low-grade lymphoma that arises from lymphoid follicles.[311,351] The

remarkable feature of these MALT lymphomas is that 80% of tumors involving only the mucosa and submucosa completely regress if *H. pylori* infection is eradicated with antibiotics.[306] Recurrence of lymphoma in 5% is associated with both recurrent infection and t(11;18) rearrangements of the immunoglobulin heavy chain.[354]

Why a scattered few people with *H. pylori* develop these rare lymphomas is unknown. Some believe that infection may precipitate an autoimmune response that predisposes to malignancy.[114,136] Others hypothesize that *H. pylori* antigens themselves may drive lymphoproliferation.[247] It is hoped that understanding the role of *H. pylori* and lymphoma will shed light not only on the pathogenesis of gastric lymphomas but on other extranodal lymphomas as well.

8.1.6. Esophageal Diseases. As *H. pylori* prevalence has diminished over time, two diseases have been on the rise: gastroesophageal reflux disease (GERD) and esophageal adenocarcinoma. Both GERD and esophageal adenocarcinoma are thought to stem, at least in part, from acid damage to the distal esophagus. Without reflux (related to obesity and structural abnormalities of the stomach and esophagus) and without acid (related to the secretory capacity of the stomach), presumably, a large proportion of GERD and esophageal adenocarcinoma would not occur. The inverse temporal correlation between *H. pylori* and esophageal distal diseases, in conjunction with the hypochlorhydria that occurs in *H. pylori*-associated multifocal atrophic gastritis, has led investigators to postulate a protective role for the organism. To date, however, no consensus has been reached on this topic. A meta-analysis of the prevalence of *H. pylori* in individuals with and without GERD identified an overall protective effect.[56,268] Significant protection was not observed in all populations, however, but seemed to predominate in Asian populations.[268] Studies on *H. pylori* eradication and subsequent development of GERD have found widely varying results but no consistent deleterious effect.[56] Two prospective studies of esophageal malignancies, in contrast, have also shown a strong protective effect of *H. pylori.*[53,125] One of these two studies evaluated only adenocarcinomas[53] whereas the other found the effect predominantly in squamous cell carcinomas.[125] Retrospective studies have often, but not unanimously, supported these findings.[352,353,354] Thus, much is left to be learned before the deleterious effects of *H. pylori* can be balanced with its somewhat more hypothetical benefits.

8.2. Diagnosis

There is no consensus on who should be tested for *H. pylori.* In their only conference on the topic—now over a decade ago—Sthe National Institutes of Health recommended that diagnostic tests for *H. pylori* be conducted in (1) all persons with active gastric or duodenal ulcer and (2) persons on maintenance histamine antagonists for prevention of recurrent peptic ulcer disease (1994). Because ulcer disease cannot be distinguished from other causes of dyspepsia on clinical grounds,[217] this approach presupposes endoscopy. Instead, many primary care clinicians favor testing for *H. pylori* in dyspeptics who fail acid inhibitory therapy, treating those infected, and offering endoscopy only to those with no response to eradication therapy. Analyses have shown that this approach is cost-effective and spares endoscopy in many individuals.[79,80] In fact, a recent, large cohort study in UK indicates that treating and screening *all* individuals, regardless of symptoms, can be cost-effective in preventing dyspepsia and its related health care costs.[79] Unless this becomes the recommendation of professional groups,[79] dyspepsia in young adults will likely remain managed via the primary care strategy above, whereas in older adults who are at risk for malignancy, endoscopy remains the approach of choice. To prevent gastric cancer, consensus groups have also recommended screening individuals with a family history of the malignancy and those with prior gastric resection.[197]

For patients undergoing endoscopy, a rapid urease test is the diagnostic test of choice. This test is less expensive and more rapid than histological examination and/or culture. For adult patients in whom endoscopy is not necessary, a stool antigen or breath test is the best option, since both can be used to assess success of treatment. Serologic assays are best used for epidemiologic studies. They have high sensitivity for ongoing infection but titers respond slowly to eradication therapy and may not regress to negative.[48,143] Diagnostic tests have not been well assessed in children. High frequency of "transient" positive tests in young children are likely, in part, to reflect inconsistent performance of these assays.

9. Control and Prevention

9.1. General Concepts

Since the mechanisms of transmission of *H. pylori* are still uncertain, there are no current recommendations for control and prevention. Based on epidemiological studies indicating person-to-person transmission, it is likely that general improvements in hygiene standards such as hand washing and good household sanitation will decrease transmission.

9.2. Antibiotic and Chemotherapeutic Approaches to Disease Prevention

H. pylori is curable with antimicrobial therapy. The two most widely use regimens are 10 days of proton pump inhibitor triple therapy (a proton pump inhibitor plus clarithromycin and either amoxicillin or metronidazole; 80–90% cure) or 2 weeks of bismuth triple therapy (a combination of metronidazole, tetracycline, and bismuth; 70–90% cure). Unfortunately, antimicrobial resistance is on the rise.[209] Although in vitro resistance to amoxicillin and tetracycline remains virtually non-existent, resistances to metronidazole and clarithromycin occur at rates of 10–15% and 20–40%, respectively. In vitro clarithromycin resistance portends a 70% decrease of treatment efficacy whereas metronidazole resistance has a somewhat less clinical significance (25% decreased treatment efficacy). Eradication failures are treated with 2 weeks of four drugs (two antibiotics, a proton pump inhibitor, and bismuth), omitting clarithromycin if it was used in the first treatment course.

Whereas consensus has been achieved on antimicrobial treatment, controversy rages over whom to treat. At their only consensus conference on the subject, the National Institutes of Health in 1994 recommended treating only persons with active ulcer disease (gastric or duodenal) or persons on maintenance antihistamine therapy for recurrent ulcer disease.[40] The 2005 European consensus from Maastricht recommended additionally treating those with non-ulcer dyspepsia, gastric lymphoma, previous gastric resection or gastric cancer, atrophic gastritis, and gastric cancer in first-degree relatives. The Maastricht consensus group further recommended treatment in anyone who wishes it.[198] Still others maintain that eradicating *H. pylori* in all those infected, regardless of symptoms, is the correct approach and a recent clinical trial supports this view as potentially beneficial though not cost-effective.[170] As new information accumulates, it is likely that diagnosis and therapy will be offered to a wider segment of the population in order to prevent adverse outcomes of infection. For now, however, there are no recommendations for diagnostic testing and/or treatment in asymptomatic persons or persons with dyspepsia of unknown etiology, particularly in regions where *H. pylori* prevalence is relatively low (<20%).

9.3. Immunization

No vaccine is currently available to prevent or treat *H. pylori* infection although vaccine development is an area of considerable interest. Because the brisk, natural immune response neither eliminates infection nor prevents reinfection, one might feel skeptical that a vaccine could be efficacious. Despite this theoretical concern, however, several candidate vaccines are beginning to show promise in animal models.[200] With advancements in our understanding of the biology, new drug targets against essential metabolic genes are also an active area of research.[281] Were such a vaccine available, it is not yet known how it would optimally be used.

10. Unresolved Problems

Since 1982, an enormous amount of research has been conducted on *H. pylori* infection. In the last 5 years alone, over 6,000 manuscripts were published. Yet many of the critical issues concerning *H. pylori* remain to be understood.

Because acute infection almost always remains undiagnosed, the infectious inoculum has not been established. Moreover, it is unknown whether host factors affect the infectious inoculum or whether all uninfected persons are equally at risk. People who have been experimentally infected have always taken acid inhibitory therapy prior to ingesting the organism. Whether hypochlorhydria is actually required to permit infection to be established is not known. Neither symptoms of naturally acquired acute infection nor transmission route are firmly established. Although there is strong, circumstantial evidence for person-to-person transmission, it is debated whether waterborne transmission also occurs.

The interplay of *H. pylori* with other disease cofactors is undoubtedly complex and will take years, if not decades, to parse out. It is assumed that differences in outcome can be explained by a combination of bacterial factors (e.g., presence of cytotoxin), environmental factors (e.g., diet, cigarettes, etc.), host factors (e.g., cytokine genotype), and temporal factors (e.g., age at acquisition of infection). The lack of relevant animal models particularly hampers understanding of these processes.

From a public health perspective, there remains no good algorithm for disease prevention. Over half of the world's population is infected with *H. pylori*. In developing countries, *H. pylori* infection is almost universal. In developed countries, on the other hand, the incidence of infection has been rapidly decreasing without any specific antibacterial intervention. Adverse outcomes of *H. pylori* infection, such as gastric cancer and ulcer disease, are also on an impressive decline. Improvements in hygiene, diet, and other socioeconomic factors, rather than antibiotic use, probably account for this favorable slope. Should we be focusing on vaccine development for a disease that disappears with improvements in hygiene? Should we be screening and treating persons in

order to prevent *H. pylori*-related diseases? Should we be treating the families of infected persons in order to interrupt the cycle of reinfection? Does *H. pylori* have any benefits? Would widespread use of antibiotics to treat *H. pylori* produce more harm in terms of the overall burden of antimicrobial resistance than good? These very fundamental issues remain to be resolved.

ACKNOWLEDGMENTS

The authors would like to thank Jeremy Schneider and Luz Sanchez for their technical assistance.

CHAPTER 19

Legionellosis

Roopal Patel, Matthew R. Moore, and Barry S. Fields

1. Introduction

Legionellosis is infection with bacteria of the genus *Legionella*. Legionellosis is primarily associated with two clinically and epidemiologically distinct syndromes: Legionnaires' disease, a potentially fatal form of pneumonia, and Pontiac fever, a self-limited, nonpneumonic illness (Table 1). At least 49 *Legionella* species and 71 serogroups have been identified, but one species, *Legionella pneumophila*, causes over 90% of Legionnaires' disease cases. The majority of *L. pneumophila* infections are caused by serogroup 1.[67] Legionellosis may occur in outbreaks or as sporadic cases (i.e., not part of a recognized outbreak). Although Legionnaires' disease outbreaks capture much media attention, the majority of reported cases are sporadic.[132] Less than 5% of cases are reported to public health authorities. Pontiac fever is generally recognized only when clusters of illness occur. Legionnaires' disease is an important cause of community-acquired and nosocomial pneumonia. At least 8,000–18,000 cases of Legionnaires' disease are hospitalized each year in the United States.[133]

2. Historical Background

Between July 21 and July 24, 1976, 4,400 visitors attended the 58th annual convention of the American Legion's Pennsylvania Department at the Bellevue-Stratford Hotel in Philadelphia. None could have known that events surrounding the meeting would be chronicled on the front pages of newspapers and in medical journals around the world. Between July 22 and August 3, 1976, dozens of conventioneers developed a mysterious febrile illness with pneumonia; no etiology was identified. During the investigation that followed, a total of 182 cases of the illness were identified among persons who had entered the Bellevue-Stratford between July 1 and August 18, 1976.[74] Many of the conventioneers became ill after returning home from the convention, yet illness was not identified among family members who had not attended the convention, indicating that it was not likely transmitted from person to person. Illness was reported for 39 additional persons who had no direct connection to either the convention or the hotel, except that all had been within one block of the Bellevue-Stratford at some time after July 1. This finding, together with the higher attack rate among convention delegates who had watched a parade from the sidewalk in front of the hotel, suggested airborne transmission of an agent in the environment. Altogether, 221 people became ill and 34 died of the illness, which became known as Legionnaires' disease. The cause of the outbreak remained unknown for 5 months despite intensive investigation, until early in 1977, when McDade and co-workers[136] recovered a fastidious, weakly gram-negative bacillus (subsequently named *Legionella pneumophila*) from guinea pigs inoculated with lung tissues of patients who had died during the outbreak. Paired acute- and convalescent-phase serum specimens from other ill conventioneers demonstrated rising levels of specific antibody to the organism, and high levels of antibody were present in over 90% of convalescent-phase specimens from ill conventioneers[7] The source of the organism at the Bellevue-Stratford was not identified.[72]

Serologic tests indicated that the newly identified organism was also the etiologic agent of earlier, unsolved outbreaks of respiratory illness and cases of sporadic pneumonia. Antibody tests performed on paired serum specimens that had been stored for several years at the Centers for Disease Control and Prevention (CDC) showed that the same

Table 1. Clinical and Epidemiological Characteristics of the Two Forms of Legionellosis

Characteristic	Legionnaires' disease	Pontiac fever
Symptoms	Fever, cough, headache, myalgia, dyspnea, chest pain, diarrhea, delirium	Fever, headache, myalgia, cough, sore throat, chest tightness
Chest X ray	Pneumonia	Normal
Primary treatment	Erythromycin	No specific therapy
Attack rate in outbreaks	<5%	>95%
Incubation period	2–10 days	<48 hours
Mortality	5–30%	None

organism, or an antigenically similar one, had caused an outbreak of 81 cases of pneumonia with 14 deaths in 1965 at a psychiatric hospital in Washington, DC.[184] Outbreaks of pneumonia occurring as early as 1957 were associated with serological evidence of legionellosis.[148] Also, a "*Rickettsia*-like" organism that had been isolated in 1947, in guinea pigs inoculated with blood of a patient with a febrile illness, was subsequently shown to be *L. pneumophila*.[135] Other organisms that had been isolated before 1976, but only partially characterized, were identified as *Legionella* species. An organism isolated from guinea pigs injected with the blood of a febrile soldier at Fort Bragg, North Carolina, in 1943, was identified as *L. micdadei*,[182] and the same agent was described in 1979 as the cause of acute pneumonia in renal transplant recipients.[150] *L. pneumophila* was also identified as the etiologic agent of an outbreak with a high attack rate of a self-limited, nonpneumonic illness with fever (Pontiac fever) occurring in 1968 at a health department building in Southfield, MI.[77] Stored lung tissue from guinea pigs that had been exposed to air in the health department building and had developed pneumonia in 1968 yielded *L. pneumophila* a decade later.[107]

The environmental source and means of transmission of the organism were unknown until 1978 when *L. pneumophila* was recovered from various environmental specimens in conjunction with investigations of outbreaks that year.[141] Aerosolized water from cooling towers and evaporative condensers (heat rejection devices used in the air-conditioning systems of large buildings) was implicated as the source of dissemination of *L. pneumophila* in outbreaks of Legionnaires' disease in Memphis and Atlanta during 1978.[46,54] In 1980, Tobin and colleagues[186] isolated the same serogroup of *L. pneumophila* from two people who developed pneumonia after receiving renal transplants in an Oxford, England, hospital and from water taken from the shower in their common hospital room, indicating the role of potable water systems in the dissemination of *Legionella* species. Subsequent investigations conducted in the 1980s and 1990s further documented the role of cooling towers and potable water systems in the transmission of legionellosis, and dissemination of legionellae from other aerosol-producing devices have been reported (see Mechanism and Routes of Transmission below).

3. Methodology

3.1. Sources of Mortality Data

The gross and microscopic pathological findings in material obtained at autopsy from patients who died of Legionnaires' disease do not differ substantially from those found in cases of severe pneumonia caused by other bacteria.[155] Direct immunofluorescent antibody (DFA) staining has been widely used to identify the organisms in lung tissue postmortem.[43,155] Monoclonal DFA reagents are designed to detect only a single species or serogroup. Polyclonal reagents but are more likely to cross-react with bacteria that may colonize the respiratory tract, such as *Pseudomonas* spp.[183] Either method of DFA testing may be performed on formalin-fixed lung scrapings, paraffin-embedded tissue sections, or fresh lung tissue,[43,155] although polyclonal reagents may be preferable for tissues fixed for prolonged periods in formalin.[58,59] A *Legionella*-specific immunohistochemical stain developed by Centers for Disease Control and Prevention (CDC) has been successful in *Legionella* identification in formalin-fixed tissue[68] and the stain is routinely used by CDC's pathology laboratory in respiratory disease outbreak investigations. Culture and polymerase chain reaction (PCR) have also been used to identify the organism in lung tissue obtained at autopsy, but care must be taken to avoid false-positive results caused by contamination during specimen processing.[120] The exact role of legionellosis in causing death may be difficult to determine because other serious, life-threatening underlying illnesses are often present. Additionally, bacteria other than *Legionella* spp. occasionally may be isolated from the lungs of persons who have died of Legionnaires' disease.

Comprehensive, systematic, and reliable data on mortality due to Legionnaires' disease are unavailable. Although the National Center for Health Statistics (NCHS) receives copies of death certificates to tabulate national figures on deaths attributed to pneumonia and influenza based on International Classification of Diseases (ICD-9) codes, identification of a specific etiologic agent is lacking in the majority of cases. Data regarding the prevalence of Legionnaires' disease among patients who have died with pneumonia have

been systematically sought in one multi-city survey of fatal nosocomial pneumonia, in autopsy surveys of one or more hospitals in a city, and in conjunction with investigations of outbreaks.[44,179] Estimates of disease incidence from these studies are limited by small sample sizes and by nonrandom selection of hospitals surveyed. Review of autopsy material during epidemic investigations has been useful for defining the magnitude of the individual outbreaks. The case-fatality rate can be estimated by determining the proportion of fatal cases among those reported through surveillance for Legionnaires' disease; however, these estimates may be inaccurate because of underreporting of cases.[132] Additionally, the diagnosis may be confirmed more often among patients who die than those who survive because of more aggressive diagnostic testing among persons with severe pneumonia.

3.2. Sources of Morbidity Data

The limited data we have on the incidence and prevalence of Legionnaires' disease in the general population are based on findings from studies of patients with community-acquired pneumonia.[21,63,71,129,133,147,162,194] The most dependable data are from studies that are prospective and population based. The findings of these studies are affected by the criteria used to identify patients for laboratory testing and the type of laboratory tests used for case confirmation. Studies of incidence and prevalence of health care-associated legionellosis[28,100,101,131,142,157] are influenced by the same factors that affect studies of patients with community-acquired infection. Additionally, the incidence of health care-associated infection varies greatly from one institution to another because of the variation in hospital facilities and patients.

Surveillance for legionellosis is conducted with varying intensity in many countries. In the United States, Legionnaires' disease is a condition reportable to the Centers for Disease Control and Prevention (CDC) through the National Notifiable Disease Surveillance System (NNDSS). Reports through NNDSS from state health departments include only basic demographic information for cases of legionellosis. A supplementary paper-based surveillance system for Legionnaires' disease collects more detailed information including whether cases are travel, health care, and/or outbreak related. However, data from prospective studies of patients with pneumonia indicate that less than 5% of legionellosis cases are reported to CDC.[132,133] The Council of State and Territorial Epidemiologists (CSTE) recently revised their position statement for legionellosis surveillance. In addition to modifying the case definition, the position statement set goals for the timeline of case reporting to improve overall surveillance and to facilitate timely identification and the subsequent investigation of travel-related cases. In Europe, over 30 countries participate in the European surveillance scheme for travel-associated Legionnaires' disease. In addition to timely reporting to the European Working Group for *Legionella* Infections (EWGLI) of travel-related cases, each year the participating countries submit standardized case report forms that provide epidemiological and microbiologic information on the total number of travel-related and non-travel-related cases. EWGLI then reports an analysis of national and European aggregate trends.[103]

3.3. Surveys

The indirect immunofluorescent antibody (IFA) test has been used most widely in serological surveys, although other, less standardized methods, including hemagglutination, indirect hemagglutination, immune adherence, microagglutination test, and enzyme-linked immunosorbent assay (ELISA), have also been used. Differences in methods of preparing test antigens and possible cross-reactions with other organisms, especially at relatively low titers, make the interpretation of serological surveys difficult. Serological tests prepared from heat-killed antigens, the most widely used test in North America, may not be as specific as those using formalinized antigen, which are commonly used in Europe.[60,61] Rates of elevated IFA titers ($\geq$ 1:128) to *L. pneumophila* in the general population have ranged from 1 to 36%[60,61,87,177]; generally, the higher rates are observed when pooled antigens from several *L. pneumophila* serogroups are used for preparation of reagents and the lower rates are seen in studies using tests specific for *L. pneumophila* serogroup 1. The relatively high background rates of elevated titers indicate that the positive predictive value of a single titer for determining recent legionellosis is low. The frequency with which legionellosis can occur as an asymptomatic or subclinical infection has been estimated by testing paired serum specimens from exposed well persons in conjunction with outbreak investigations.[56]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification. *Legionella* cannot be cultured by routine clinical bacteriologic techniques. Charcoal yeast extract agar is the base form for most media used to grow legionellae.[65] The medium used for the culture of legionellae has been improved several times, eventually resulting in the medium currently used, buffered charcoal yeast extract (BCYE) agar enriched with α-ketoglutarate with and without selective agents added.[57] BCYE agar plates are incubated at 37°C in an atmosphere of 2.5%

CO_2. Legionellae require 3–14 days to grow. *Legionella*-like colonies are identified using a dissecting microscope and light source to detect colonies resembling legionellae. After approximately 4 days of incubation, these colonies are 2–4 mm in diameter, convex, and round with entire edges. The colonies are usually white in the center bordered with blue, purple, green, or red iridescence. Colonies resembling legionellae can be presumptively identified on the basis of their requirement for the amino acid L-cysteine by subculture on blood agar or BCYE agar without L-cysteine. Subcultured colonies that grow on BCYE agar, but not on blood agar or BCYE without L-cysteine, are presumed to be legionellae. Definitive identification is usually accomplished by using a direct fluorescent antibody (DFA) or slide agglutination test with specific antisera.

Culture remains the gold standard for diagnosing legionellosis and for identifying the organism in the environment. Based upon culture of serologically positive (4-fold rise) patients, the sensitivity is near 60% and the specificity is near 100%.[58,59,123] However, a number of factors limit the sensitivity of culture. Laboratories experienced in the isolation of legionellae are more likely to recover the organism. A survey by the College of American Pathologists indicated that as many as two thirds of clinical microbiology laboratories in the United States are unable to grow a pure and heavy culture of *L. pneumophila*.[60,61] Moreover, to improve the specificity of the diagnosis of pneumonia caused by pyogenic bacteria, a common practice in hospital laboratories is to reject sputum specimens containing many squamous epithelial cells or few polymorphonuclear leukocytes; however, some patients with Legionnaires' disease produce little or nonpurulent sputum, and sputum specimens that would be routinely discarded may contain culturable legionellae.[95] The bacteria survive poorly in respiratory secretions, and immediate culture of these specimens is critical.[67] The reported sensitivity of culture ranges widely from 20 to 80%, reflecting the perishable nature of the specimens and the expertise required.[158]

Legionellae can be isolated from a number of specimens, including blood, lung tissue, lung biopsy specimens, respiratory secretions (sputum, bronchial alveolar lavage (BAL) bronchial aspirates), and stool. Respiratory secretions are considered the specimens of choice. Sputum is considered less suitable than other respiratory secretions, especially in early disease when few patients have a productive cough.[123] When culturing sputum it is best to pretreat the sample by either acidification or heat. *Legionella* has also been cultured from a number of extrapulmonary sites such as bone marrow, prosthetic heart valves, and sternal wounds.[55,60,61] Several guidelines give detailed methods for the isolation of *Legionella* from clinical samples.[55,178,188]

3.4.2. Serological Diagnostic Methods. Although serological tests are widely used for the diagnosis of legionellosis, these tests have a number of important and often under-recognized limitations. Even in cases of culture-confirmed Legionnaires' disease, a 4-fold rise in antibody by IFA can be documented for only 70–80% of patients, and seroconversion following legionellosis may not occur for up to 2 months following the onset of illness.[60,61] Reagents that detect all major immunoglobulin classes (IgG, IgM, and IgA) are generally used. Testing for IgM alone has not proved useful for the diagnosis of legionellosis because IgM often increases concomitantly with IgG and may remain elevated for months or years after infection.[33] A single elevated antibody titer does not confirm the diagnosis of legionellosis. In a large study of patients hospitalized with community-acquired pneumonia in Ohio, a single titer of $\geq$ 1:256 did not distinguish between Legionnaires' disease and pneumonia due to other agents: only 10% of 68 patients with legionellosis confirmed by culture or 4-fold rise in antibody had acute-phase titers of $\geq$256 compared with 6% of 636 patients with pneumonia caused by other agents.[153] Current recommendations suggest the use of *L. pneumophila* serogroup 1 antigen only and the avoidance of polyvalent antigen pools. It is extremely difficult to make a diagnosis based on results of IFA tests with polyvalent pools.

Microscopic examination of specimens using DFA staining can be used to detect legionellae in lung tissue (from autopsy or biopsy) and in respiratory secretions. The sensitivity of DFA testing of respiratory secretions for the diagnosis of Legionnaires' disease has ranged from 25 to 75%, and specificity is >95%.[60,61] While DFA provides a rapid method of identifying *Legionella* spp., immunofluorescent microscopy is technically demanding and should be performed only by laboratory personnel experienced in the procedure. The specificity of polyvalent DFA reagents is probably lower than that of monoclonal reagents, leading some clinical microbiologists to recommend against routine use of polyvalent reagents.[60,61] Legionellae can be detected in respiratory secretions by DFA for several days after the start of antimicrobial therapy.

3.4.3. Urine Antigen Detection. Urinary antigen testing has led to the recognition of outbreaks of Legionnaires' disease and allowed for rapid public health response.[62,68,117] In addition, urine antigen testing permits early diagnosis and initiation of appropriate antibiotic therapy. The capture antibody used in the majority of these assays is considered to be specific for *L. pneumophila* serogroup 1. Therefore, even though the majority of human diseases are associated with *L. pneumophila* serogroup 1,

total dependence upon this diagnostic assay may miss as many as 40% of the cases of legionellosis. *Legionella* antigen present in urine specimens appears to degrade upon prolonged storage.[156] There is a single report of a false-positive urinary antigen assay on a specimen obtained from a renal transplant patient who had received rabbit serum with antibodies to thymocytes.[48]

Changes in the use of diagnostic tests for Legionnaires' disease may have had an impact on the number of reported cases, the reported mortality, and the distribution of serotypes. In the United States, cases diagnosed by culture have declined while cases diagnosed by urine antigen have increased. Since urine antigen testing allows for earlier diagnosis, this may have allowed for more appropriate antimicrobial therapy and improved the outcome of Legionnaires' disease. However, since urine antigen testing primarily detects serogroup 1 infections, cases of Legionnaires' disease caused by other serogroups and species may have been missed.[14]

Shortly after the outbreak of Legionnaires' disease at the American Legion Convention in Philadelphia, investigators reported the ability to detect antigen in the urine of serologically confirmed Legionnaires' disease patients by ELISA.[18,185] The antigen detected is a component of the lipopolysaccharide portion of *Legionella* cell wall and is heat stable.[111,191] Antigens are generally detectable in urine within a few days of illness onset and can remain so for several weeks after initiation of appropriate antimicrobial therapy.[110] These studies have shown that antigen is excreted as soon as 3 days after the onset of symptoms and can persist for >300 days. Antigens detected in 88% of patients tested during days 1–3, 80% during days 4–7, 89% during days 8–14, and 100% after day 14 were positive.

Currently, there are three commercially available ELISA urinary antigen tests: Wampole (formerly distributed by Binax, Inc.), Cranbury, New Jersey; Trinity Biotech, Ireland; and Biotest AG, Dreieich, Germany. Two of these tests (Wampole and Trinity Biotech) are intended to be specific for *L. pneumophila* serogroup 1 and are not likely to detect the 20–30% of Legionnaires' disease cases that are caused by other serogroups and species.[123] The Biotest ELISA is intended to detect antigen of other *L. pneumophila* serogroups and *Legionella* species.

The most recent method for detecting antigenuria is the immunochromatographic (ICT) membrane assay. The ICT assay is similar to a home pregnancy test and is commercially available (NOW *Legionella* urinary antigen test, Binax, Inc., Portland, ME). The test is simple to perform, does not require special laboratory equipment, and results can be obtained within 15 minutes. A comparison of the Binax NOW with the Binax EIA showed 98% overall agreement between the two tests and a specificity of 100%.[52] The authors suggested using concentrated urine samples to increase test specificity. Another study determined that the sensitivity of the ICT assay for *L. pneumophila* serogroup 1 was 80% and the specificity 97%.[86]

3.4.4. Nucleic Acid Detection. Polymerase chain reaction (PCR) represents one of the few diagnostic tests with the potential to detect infections caused by all of the known species of *Legionella*. Since most rapid tests only detect infections due to *L. pneumophila* serogroup 1, an accurate PCR test would greatly enhance the ability to diagnose these infections. Various PCR tests have been developed for legionellae targeting several genes.[67] A limited number of laboratories test for legionellae by PCR at this time. The few studies which have been conducted indicated that the PCR detection of legionellae infections has a moderate sensitivity and a high specificity. Legionellae DNA has been detected in respiratory secretions such as BAL, pharyngeal swabs, nasopharyngeal swabs, peripheral blood mononuclear cells, urine, and serum.[67]

Numerous studies have reported development of real-time PCR combined with the use of a hybridization probe to confirm the product identity.[11,78] These methods reduce the risk of cross-contamination, the time to process samples, and eliminate the need for sample analysis after PCR. Limited studies and preliminary data suggest that PCR may add to the diagnostic repertoire, but this procedure may lack the sensitivity and specificity to provide anything other than supplemental data for the clinician.

3.4.5. Biological Characteristics of the Organism. Bacteria of the genus *Legionella* are gram-negative, aerobic, rod-shaped bacteria. The bacterial cells are 0.3–0.9 by 1–20 μm and motile, with one or more polar or lateral flagella.[29] Currently, there are 49 species comprising 71 distinct serogroups in the genus *Legionella*.[15,67,149] One species, *L. pneumophila*, causes approximately 90% of all reported cases of legionellosis in the United States. This figure may be inflated as most diagnostic tests are specific to *L. pneumophila*. Approximately half of the 49 species of legionellae have been associated with human disease and it is likely that many of the rest can cause disease under appropriate conditions.

Legionellae use amino acids as their carbon and energy sources and do not oxidize or ferment carbohydrates.[66] The bacteria can be grown in the laboratory on buffered charcoal yeast extract (BCYE) agar. This is a complex medium supplemented with soluble iron and the amino acid cysteine. These fastidious growth requirements are reflect the bacteria's existence as a facultative intracellular parasite of eukaryotic cells. Legionellae multiply intracellularly

in freshwater protozoa in the environment and in monocytes and alveolar macrophages of humans.[66] Legionellae are readily phagocytized by alveolar macrophages and monocytes and are able to multiply intracellularly within specialized phagosomes.[94] Large numbers of organisms can be visualized and recovered from the lungs of patients with Legionnaires' disease; however, the organism does not appear to asymptomatically colonize the respiratory tract.[30] Therefore, any *Legionella* species recovered from respiratory secretions should be viewed as a likely pathogen. Infection of both human phagocytic cells and freshwater protozoa is accomplished utilizing a type IVB secretion system composed of 25 genes.[166] This type IV secretion system delivers substrates which allow the bacteria subvert host cell processes for its own propagation.

Water is the major reservoir for legionellae, and the bacteria are found in freshwater environments worldwide.[70] Legionellae have been detected in as many as 40% of freshwater environments by culture and in up to 80% of freshwater sites tested by PCR.[67] A single exception to this observation is *L. longbeachae*, a frequent isolate from potting soil.[175] This species is the leading cause of legionellosis in Australia and occurs in gardeners and those exposed to commercial potting soil.[161] The first US cases of *L. longbeachae* infection associated with potting soil were reported in 2000.[39] *L. pneumophila* multiplies at temperatures between 25 and 42°C, with an optimal growth temperature of 35°C.[106] Most cases of legionellosis can be traced to man-made aquatic environments where the water temperature is higher than ambient temperature. Thermally altered aquatic environments can shift the balance between protozoa and bacteria, resulting in rapid multiplication of legionellae, which can translate into human disease.

4. Descriptive Epidemiology

4.1. Incidence and Prevalence

Surveillance for legionellosis does not yield an accurate measure of incidence because many cases are not diagnosed or reported. Furthermore, only a few population-based studies have assessed the incidence of legionellosis. In a population-based study of all adults hospitalized during 1991 with pneumonia in two counties in Ohio, the annual incidence of Legionnaires' disease was 7.0 cases per 100,000 adults.[133] After projecting the age- and race-specific incidence to the US population, the study estimated that 8,000–18,000 cases of Legionnaires' disease are hospitalized annually. This estimate is much greater than the number of cases reported to the CDC through the NNDSS each year which ranges from 1,200 to 2,000 cases.[41] The difference in the number of reported cases and estimated incidence may be due to several factors. Cases may be diagnosed but not reported to the state public health department or from the state to CDC. Or more often, cases may not be diagnosed because LD testing was not performed. In a study of patients participating in a prepaid health plan that covered 10% of the population in Seattle, Washington, 5 (1%) of 500 patients with community-acquired pneumonia (84% treated as outpatients) evaluated between 1963 and 1975 had legionellosis confirmed by a 4-fold rise in antibody titer.[71] Based on these findings, the annual incidence of legionellosis was estimated to be 12 cases per 100,000 persons (95% confidence interval: 4–28 per 100,000).[71] A much lower incidence was observed in a 1-year, community-based study in Nottingham, England (population approximately 70,000): Of 251 patients with pneumonia (78% managed without hospitalization), only 1 had legionellosis confirmed by serological testing, for an annual incidence of 1.4 cases per 100,000 persons.[194] A more recent prospective study in Barcelona, Spain, showed similar results (3.3 cases per 100,000 persons),[5] again lower than the incidence seen from studies in the United States. Results from population-based studies that focus on outpatients with community-acquired pneumonia underestimate the true incidence of Legionnaires' disease since the majority of LD infections are severe enough to require hospitalization.

The overall proportion of hospital-acquired pneumonia due to Legionnaires' disease is not known, although the percentage at individual hospitals has ranged from 0 to nearly 50%.[100,101,131,142,157,162] Of the cases reported to the CDC through the supplementary paper-based system, 35% are considered to be health care associated.[14] Surveillance data from the European Working Group for *Legionella* infections from 28 to 32 countries in 2000–2002 found that 8.6% of the total cases were health care associated.[103]

No data are available on the incidence or prevalence of Pontiac fever. Surveillance for Pontiac fever, although a part of NNDSS, is difficult because symptoms are often mild and nonspecific, and no rapid tests are available to confirm the diagnosis. Most reported Pontiac fever cases are outbreak related. Sporadic cases, if they occur, are not identified and little is know about them.

4.2. Epidemic Behavior and Contagiousness

Although 80–90% of legionellosis cases reported through surveillance in the United States and the United Kingdom are sporadic,[132] Legionnaires' disease can occur in explosive, common source outbreaks. Risk factors for

legionellosis have been identified primarily from epidemiologic investigations conducted in outbreak settings. Ongoing or recurrent outbreaks occurring over a period of years have been associated with exposure to colonized water systems in hotels and hospitals.[13,19,51] During outbreaks of Legionnaires' disease, attack rates among those exposed to the source of the organism are generally less than 5%, while the attack rate for Pontiac fever is much higher, up to 95% of exposed persons become ill.[91] In outbreaks of legionellosis, the risk of illness is often associated with the amount of time spent in the area of apparent exposure and, for Legionnaires' disease, but not Pontiac fever, the level of host susceptibility.

Although the organism is present in the respiratory secretions of patients with Legionnaires' disease, person-to-person transmission has not been documented. To assess the possibility of person-to-person transmission during the 1976 outbreak in Philadelphia, interviews were conducted with 193 household contacts of persons with Legionnaires' disease; no cases of illness suggestive of secondary spread during the 3 weeks following exposure were identified.[74] Similar interviews were conducted with household and hospital contacts of 27 patients during the investigation of an outbreak in Kingsport, Tennessee, in 1977; no evidence of person-to-person transmission was found.[53] Yu and colleagues found no instances of pneumonia or seroconversion to *L. pneumophila* among 17 household contacts of patients with community-acquired Legionnaires' disease or among 15 hospital roommates of patients with nosocomial infection.[196] There was no evidence of transmission of *L. pneumophila* from symptomatic, experimentally infected guinea pigs to uninfected animals in adjacent cages located <1 in. away.[105] One investigation found a higher prevalence of unexplained febrile respiratory illnesses and elevated antibody titers to *L. pneumophila* among hospital personnel in contact with Legionnaires' disease patients compared with health care workers without such exposure,[164] but these findings have not been reproduced. The elevated antibody levels among contacts of persons with legionellosis may reflect common exposure to an environmental source of the organism rather than person-to-person transmission, and the higher prevalence of self-reported respiratory illnesses among persons also reporting exposure to infected patients may be due to recall bias.

4.3. Geographic Distribution

Legionellosis occurs worldwide. Although most surveillance data are reported by countries in temperate regions, cases of Legionnaires' disease have been identified in tropical countries when diagnostic testing has been performed.[2,119] In the United States, the incidence of reported Legionnaires' disease cases varies greatly among the states, with higher rates observed in some northern states.[132] The observed regional variation in incidence may be due to dissimilar diagnostic and reporting practices or may reflect actual differences in incidence resulting from disparate ecological or epidemiological factors.

4.4. Seasonal Distribution

Rates of reported Legionnaires' disease cases vary seasonally, with the highest rates occurring during the summer months[132]; outbreaks of Legionnaires' disease associated with cooling towers often have occurred during the summer and fall months.[17] Nonetheless, during a prospective, population-based study of pneumonia in Ohio, where diagnostic tests for legionellosis were systematically obtained, cases of Legionnaires' disease were identified year-round without an excess of cases in the summer.[133] Thus, the reported seasonality of Legionnaires' disease could reflect an ascertainment bias, i.e., clinicians may suspect and order tests for legionellosis more frequently during the summer on the basis of early reports of Legionnaires' disease as a predominantly summer disease.[133]

4.5. Age

In the 1976 outbreak in Philadelphia and in many subsequent Legionnaires' disease outbreaks, attack rates increased progressively with increasing age.[74] The incidence of Legionnaires' disease identified through surveillance is highest among persons 70–79 years of age with a median age of 60 years.[14] The association between illness and advanced age may be confounded by the high prevalence of medical conditions that predispose to Legionnaires' disease among the elderly. Compared with adults, Legionnaires' disease appears to be an uncommon cause of pneumonia among children. Most reported cases of Legionnaires' disease in children were nosocomial infections that occurred in patients who had underlying immunosuppressive conditions.[34] However, seroconversion to *L. pneumophila* without respiratory disease is not uncommon during early childhood.[6] It is not clear whether these asymptomatic seroconversions among young children reflect frequent exposure to the organism or infection with serologically cross-reacting organisms.

Most information regarding the demographics of cases of Pontiac fever comes from outbreak investigations. In the

largest reported Pontiac fever outbreak in the past 10 years, the mean age of the cases was 37 years but the range was 4–76 years.[102]

4.6. Sex

Legionnaires' disease occurs more often among men than women.[132] It has not been determined whether this is the result of greater susceptibility, higher prevalence of certain predisposing conditions (e.g., cigarette smoking, chronic lung diseases), more diagnostic testing, or increased risk of exposure. Serosurveys have generally not demonstrated differences in prevalence of elevated titers to *L. pneumophila* among men and women,[154,177] although one study found a greater prevalence of reciprocal titers $\geq$128 among men aged 40 years and older compared with women in the same age range.[87] In outbreaks of Pontiac fever, attack rates among exposed males and females are approximately equal.

4.7. Race

During outbreaks, no consistent association between race and risk of legionellosis has been observed. One study found that the risk of community-acquired Legionnaires' disease was 14-fold higher among blacks than whites,[176] but among persons with Legionnaires' disease reported through surveillance during the 1980s and 1990s, there was no difference in the rate of disease among the races.[14]

4.8. Occupation

Outbreaks of legionellosis have occurred in a variety of workplace settings, including industrial plants[36,76,88] and office buildings.[45,75] Additionally, employees working in hospitals where transmission of Legionnaires' disease was occurring have become infected.[84,108] The relative importance of workplace exposure as a setting for transmission of non-outbreak-related legionellosis is unknown.

No particular occupation has been consistently identified as posing an increased risk of legionellosis. Construction workers were found to be at higher risk of sporadic Legionnaires' disease in one case–control study,[176] but a serological survey did not show a higher prevalence of elevated antibody titers to *L. pneumophila* among construction and other outdoor workers compared with white-collar personnel working indoors.[173] A survey comparing air-conditioning maintenance personnel with workers for the same company who had no direct exposure to cooling towers demonstrated no differences in history of pneumonia or elevated titers to *L. pneumophila* serogroup 1.[81] While one study found a higher prevalence of antibody to *L. pneumophila* among workers with greater exposure to colonized power plant cooling towers,[32] another study failed to demonstrate such a difference.[50] Asymptomatic maintenance employees who worked on air-conditioning cooling towers associated with an outbreak of Legionnaires' disease were more likely to have serological evidence of infection compared to co-workers with less exposure.[109]

4.9. Occurrence in Special Settings

4.9.1. Health Care-Associated Infection. Legionnaires' disease is an important and often under-diagnosed cause of health care-associated pneumonia. Hospitals provide a unique setting for the increased transmission of Legionnaires' disease because complex plumbing systems favor amplification of *Legionella* and large numbers of persons with underlying medical conditions may be exposed to the organism. Numerous outbreaks of health care-associated disease have been reported,[7,10,19,23,26,28,35,51,54,77,83,84,100,101,104,109,134,137,142,146,169,184,186,187] and exposures to aerosols generated by cooling towers, showers, faucets, and respiratory therapy equipment with contaminated potable water have been implicated. Aspiration of *Legionella*, especially among patients with nasogastric tubes or impaired swallowing reflexes, likely occurs. Transmission within hospitals with colonized hot water systems can occur intermittently for years.[19,51,114] In one hospital in Arizona, after three possible nosocomial cases were identified in a 3-month period, increased retrospective and prospective surveillance found 25 cases in over a 17-year period. Environmental studies implicated chronic colonization of the hospital potable water system as the source of these cases.[114]

The risk of acquiring Legionnaires' disease during hospitalization is influenced by a number of factors, including the type and intensity of exposure and the health status of the exposed.[41] Specific risk factors for nosocomial Legionnaires' disease include immunosuppressive medication (e.g., cytotoxic chemotherapy, corticosteroids), endotracheal intubation, general anesthesia, placement of a nasogastric tube, and occupying a hospital room near an aerosol source.[7,23,26,35,83,84,142] Showering was associated with nosocomial legionellosis in one study,[26] while another found showering to be significantly less common among patients with hospital-acquired infection.[23] The lack of consistent association with showering likely reflects different modes of transmission in various hospital settings.

4.9.2. Disease among Travelers. A history of recent travel is associated with approximately 21% of Legionnaires' disease cases in the United States[14] and 30% from European surveillance[103] are associated with recent travel. In a case–control study of sporadic community-acquired Legionnaires' disease in the United States, case-patients were more likely to have traveled during the 2 weeks before illness onset than were their acquaintances.[176] Outbreaks of legionellosis have been identified among guests at hotels and resorts and among passengers on cruise ships.[13,42,74,80,90,98,125,138,165] Outbreaks of Legionnaires' disease among travelers are under-recognized. Hotel guests and cruise ship passengers exposed during travel often return home before becoming ill; unless several members of the same travel party become ill, the clustering of cases and the association with travel may not be recognized. Pontiac fever outbreaks related to travel may be detected more readily because of the higher attack rate and shorter incubation period.

4.10. Socioeconomic Factors

Although socioeconomic status may be linked with risk factors for legionellosis (e.g., smoking, travel, underlying illness), a direct association between socioeconomic status and the risk of legionellosis has not been identified.

4.11. Other Factors

4.11.1. Cigarette Smoking. Cigarette smokers have a 2- to 4-fold increased risk of developing Legionnaires' disease than do nonsmokers, and the risk is greatest among more frequent smokers.[132,176] Alveolar macrophages harvested from healthy smokers have diminished resistance to intracellular replication of *L. pneumophila* compared with those from nonsmokers.[97] Cigarette smoking has not been associated with Pontiac fever.

4.11.2. Alcohol Consumption. Compared with cigarette smoking, alcohol consumption has been less consistently associated with Legionnaires' disease, and the association may be confounded by the higher prevalence of smoking among those who drink alcohol heavily.[96] After controlling for smoking in multivariate analysis, one study of sporadic, community-acquired disease demonstrated an increased risk of infection among persons who consumed three or more alcohol-containing drinks per day.[176]

4.11.3. Underlying Medical Conditions. The risk of acquiring Legionnaires' disease is over 20-fold greater for persons with hematologic malignancies or with end-stage renal disease than for the general population.[132] Risk of disease is also heightened for persons with diabetes mellitus or lung cancer and for patients receiving corticosteroids.[7,35,83,132,176] Legionnaires' disease is increasingly recognized in persons with acquired immunodeficiency syndrome (AIDS).[22] Results from a small number of cases reported through surveillance showed that the incidence of Legionnaires' disease among persons with AIDS is more than 40 times that of the general population.[132] However, in the largest series of Legionnaires' disease in patients with HIV reported, no statistically significant difference in outcome was found between patients with and without HIV, although there was a trend toward a worse outcome in the HIV-positive patients.[152] Pontiac fever does not have a predilection for persons with underlying illness.

5. Mechanism and Routes of Transmission

Inhalation of legionellae in aerosolized droplet nuclei is the primary means of transmission for legionellosis.[24] These aerosolized droplets must be of a respirable size (1–5 μm). A number of devices have been implicated as sources of aerosol transmission of legionellae (Table 2). These sources are associated with both potable and non-potable water. Sources producing aerosols of contaminated potable water include showers, faucets, and respiratory therapy equipment.[26,134] Sources using non-potable water

Table 2. Aerosol Sources for Transmission of Legionellosis Identified During Outbreak Investigations

Clinical syndrome	Aerosol source	Selected references
Legionnaires' disease	Cooling tower	(54, 12, 85, 109, 77, 1, 37)
	Evaporative condenser	(46, 26)
	Showers	(186, 84, 87)
	Faucets	(27)
	Respiratory therapy equipment	(7, 134)
	Portable room humidifier	(7)
	Whirlpool spa	(190, 98, 38)
	Decorative fountain	(90)
	Ultrasonic mist machine	(122)
Pontiac fever	Cooling tower	(74)
	Evaporative condenser	(107)
	Whirlpool spa	(174, 127, 80, 138)
	Decorative fountain	(90)
	Industrial metal work	(88, 76)
	Industrial cleaning processes	(73, 36)

include cooling towers, heated spas, decorative fountains, humidifiers, ultrasonic mist machines, and industrial manufacturing systems.[49,76,82,102,122] The role of home humidifiers in sporadic cases of Legionnaires' disease is unknown. Ducts and vents of air-conditioning systems can be conduits for passage of aerosol-containing *Legionella* organisms from nearby contaminated cooling towers. Most studies have indicated that aerosol from contaminated cooling towers can transmit disease within a limited range (<200 m); however, in certain circumstances, cooling towers may transmit *Legionella* to persons over longer distances.[1] Air-conditioning systems based on direct exchange of heat from refrigerant to air, without use of water evaporation (such as window and most other home air-conditioning units and automobile air conditioners), are not capable of transmitting disease. Legionellosis resulting from aspiration of upper respiratory secretions or gastric contents may occur among certain hospitalized patients.[100,101] Transmission of extrapulmonary *L. dumoffii* infection by direct inoculation of surgical wounds with colonized tap water during bathing or dressing changes has been reported.[121] Meaningful identification of sources of transmission requires a multidisciplinary approach including epidemiology, molecular epidemiology, and microbiologic techniques such as water and, occasionally, air sampling.

6. Pathogenesis and Immunity

The incubation period for Legionnaires' disease is generally 2–10 days from exposure until onset of pneumonia symptoms,[91] although incubation periods of 14 days or longer have been reported.[49,74] Inhaled organisms that reach the terminal alveoli are engulfed by alveolar macrophages and reside within specialized phagosomes that do not fuse with lysosomes, permitting the organism to escape intracellular killing.[92] Animal studies indicate that *L. pneumophila* replicates rapidly within 24 hours after infection[47]; large numbers of organisms are released from infected macrophages and, in turn, enter other phagocytes. Legionellae also appear to be capable of reproducing within alveolar epithelial cells, but the significance of this observation is not known.[139] An influx of polymorphonuclear leukocytes into the lungs occurs during the initial 3 days of infection, followed by an infiltration of mononuclear phagocytes.[47] Viable organisms are cleared from the lungs of surviving animals within 11 days of infection, and clearance coincides with the appearance of antibodies to *Legionella* in serum and alveolar lavage fluid.[47]

The gross pathological findings in Legionnaires' disease include heavy, congested lungs with consolidation distributed evenly through the lung parenchyma with no predilection for any specific lobe.[20,192] Consolidation is usually delineated by the lobular septa. In some cases, consolidation is distinctly nodular and may be mistaken for tumor nodules. Cut surfaces of involved portions of lung appear moist and airless. Although pulmonary cavities are rarely identified radiographically with Legionnaires' disease, multiple small macroscopic lung abscesses are observed in approximately 20% of fatal cases. Overtly hemorrhagic pulmonary parenchyma and empyema are unusual.

Microscopically, there is an acute fibropurulent pneumonia with neutrophils, macrophages, erythrocytes, and fibrin that fill the alveoli and respiratory bronchioles; these findings do not differ substantially from those of bronchopneumonia caused by other bacteria.[19,157] Superimposed features of diffuse alveolar damage, such as hyaline membranes, interstitial inflammation, and pneumocyte regeneration, may be present in severe cases. Although the cellular infiltrate is commonly necrotic and small abscess formation may occur, the underlying pulmonary structure remains intact. Legionellae are difficult to identify by Gram's stain, but will stain nonspecifically with Giemsa, Warthin–Starry, and Dieterle techniques.[19] Bacilli are commonly seen in clusters within macrophages. *L. micdadei* and *L. cincinnatiensis* in clinical specimens may stain with acid-fast techniques (e.g., Kinyoun stain), but will appear morphologically distinct from mycobacteria.[89,99,193]

Bacteremia may accompany Legionnaires' disease,[9] but whether symptoms referable to the gastrointestinal tract, kidneys, central nervous system, and muscle result from direct bacterial invasion (which has rarely been demonstrated in extrathoracic organs), toxins, or other indirect effects is not known. No consistent histopathologic changes have been demonstrated outside the lungs.

Cell-mediated immunity is important in host defense against legionellae, which multiply in human blood monocytes and alveolar macrophages.[92,145] Three different types of cellular responses contributing to immunity have been studied.[93] First, human monocytes and alveolar macrophages activated by lymphokines inhibit intracellular multiplication of *L. pneumophila*. Second, activated polymorphonuclear leukocytes have an enhanced capacity to kill the organism, although several days are required for killing, raising some questions about the significance of this immune mechanism. Third, cytotoxic lymphocytes may be capable of lysing infected macrophages, although evidence supporting this mechanism has not been reproduced.[93] Moreover, patients receiving medications that impair cell-mediated immunity are at increased risk of Legionnaires' disease. These observations suggest that cell-mediated immunity is the primary host defense against legionellosis, while humoral

immunity plays a secondary role. Anti-*L. pneumophila* antibody promotes phagocytosis of the organism by alveolar macrophages but does not promote intracellular killing.[145]

The level of protection against reinfection among humans after legionellosis is poorly understood. Guinea pigs exposed to sublethal doses of *L. pneumophila* in aerosols developed strong humoral and cell-mediated immune responses, and these animals survived subsequent challenge with large doses of aerosolized *L. pneumophila*, which killed control animals that were not previously exposed.[28]

Pontiac fever usually has an incubation period of less than 48 hours after legionellae are inhaled.[79] The pathogenesis of this syndrome is not understood, in part because the disease is not fatal and no pathological material has been examined. It is also unknown whether proliferation of bacteria is necessary to produce the syndrome and, if it is, where the proliferation occurs. Hypersensitivity to inhaled amoebae that are infected with legionellae has been proposed as a possible cause of Pontiac fever.[36,160]

7. Patterns of Host Response

7.1. Clinical Features

Legionnaires' disease is a type of pneumonia that may also involve other organ systems. Clinical features may include fever, cough, headache, myalgia, dyspnea, pleuritic chest pain, diarrhea, and delirium. The white blood cell count is normal or elevated, with an increased proportion of immature neutrophils. Chest radiographs of patients with Legionnaires' disease typically show alveolar infiltrates, although a variety of radiographic patterns may be seen. Pleural effusions, when present, are typically small. Cavitation of pulmonary infiltrates occasionally occurs, particularly in immunosuppressed patients.

The severity of illness in legionellosis ranges from asymptomatic seroconversion to rapidly fatal pneumonia. Among patients with at least a 4-fold rise in antibodies to *Legionella* after admission to hospitals where ongoing nosocomial transmission was occurring, 29–69% had no evidence of pneumonia.[56] Mortality in Legionnaires' disease outbreaks has ranged from 5 to 30%.[91] Among cases reported through surveillance, 24% were fatal.[132] Death occurs due to progressive pneumonia with hypoxemia and shock. Factors associated with a fatal outcome include advanced age, immunosuppression, nosocomial acquisition, end-stage renal disease, and cancer.[132] Historically, the drug of choice for treatment of Legionnaires' disease was erythromycin. However, reports of treatment failures with erythromycin have led to the evaluation of other antibiotics[163] and a change in the treatment recommendations. Infectious Diseases Society of America guidelines for treatment of community-acquired pneumonias recommend the use of fluoroquinolones or azithromycin for patients with Legionnaires' disease.[126] Convalescence following Legionnaires' disease may be prolonged in some cases, with weakness and shortness of breath persisting for months. Residual defects in pulmonary diffusing capacity have been observed.[116] Reinfection with *L. pneumophila* has been reported for severely immunocompromised patients.[118] Manifestations of disease caused by *L. pneumophila* and by other species of *Legionella* appear to be similar.[64]

Extrapulmonary infections during the course of Legionnaires' disease have been recognized, most likely due to bacteremic seeding during the course of pneumonia. Reported extrapulmonary infections with *Legionella* spp. in the absence of clinically apparent pneumonia include involvement of the endocardium, pericardium, peritoneum, bowel, respiratory sinuses, and skin and soft tissues.[60,61] Extrapulmonary disease generally occurs in immunosuppressed patients.

Pontiac fever is an acute illness characterized by fever, headache, and myalgia. Cough, sore throat, and chest tightness are observed in about 50% of cases.[79] Other symptoms occasionally reported include dizziness, nausea, confusion, and a burning sensation in the eyes. No specific therapy is required for Pontiac fever. Illness may be debilitating for several days, but recovery is usually complete within 1 week. Prolonged effects of Pontiac fever have been suggested though studies with sufficient follow-up are limited.[36]

8. Control and Prevention

8.1. General Concepts

The risk of developing *Legionella* infection from an aquatic environment depends on several factors including conditions that support amplification of the organism, a mechanism of exposure (e.g., aerosolization of colonized water), and transmission to hosts with risk factors for development of disease. Approaches to the control and prevention of legionellosis involve strategies that may interfere in any of the steps from colonization of a water system by *Legionella* to transmission of disease.

The approach to the prevention of legionellosis can take two forms. Primary prevention involves the control of *Legionella* in a water system before the detection of disease. Secondary prevention focuses on eradication of *Legionella* from aquatic systems once cases of legionellosis have been recognized.

Strategies for primary prevention should create conditions that are unsuitable for bacteria amplification and dissemination to occur. Certain characteristics of legionellae can be exploited to control and eradicate the organism. Legionellae grow poorly at temperatures below 20°C or above 50°C and are readily killed at temperatures above 60°C.[67] Additionally, legionellae are susceptible to a broad range of disinfectants, including chlorine- and bromine-containing compounds, ozone, heavy metal ions, and ultraviolet light.[115,143,172] Sound engineering design and regular maintenance of water systems are also key to the control of *Legionella* growth. The American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE) has issued guidelines for the control of *Legionella* in buildings. For cooling towers ASHRAE recommends regular maintenance, the use of a biocidal treatment program, and the use of the services of a qualified water treatment specialist to determine and oversee the treatment program (8). Additional strategies for primary prevention include placement of towers as far from building air intakes and public areas as possible and the use of drift eliminators to minimize aerosol dissemination.[31]

For secondary prevention in situations where cooling towers have been implicated in outbreaks of Legionnaires' disease, remediation can be complex and requires the assistance of experts in these processes. Methods that have been successful in preventing further transmission in outbreak settings include hyperchloridation and mechanical cleaning.[180]

A number of methods have been used to eradicate legionellae from potable water systems.[144,180] In buildings where the heated water system has been identified as the source of Legionnaires' disease outbreaks, those systems have been decontaminated by thermal disinfection (i.e., flushing each distal outlet of the hot water system with water at 71–77°C) or hyperchlorination (flushing all outlets of the hot water system with water containing 1–2 mg/l free residual chlorine at the tap), and transmission has been interrupted. Following either of these procedures, hot water should be stored at a temperature 60°C and circulated with a minimum return temperature of $\geq$51°C. Cold water should be stored and circulated at $<$20°C.[7] Disadvantages of thermal eradication include the risk of scalding. Supplemental chlorination has caused accelerated corrosion and leaks in plumbing systems and could lead to formation of potentially carcinogenic halogenated organic compounds.[144] Additional measures, such as physical cleaning or replacement of hot water storage tanks, water heaters, faucets, and shower heads, may be required to remove accumulated scale and sediment that protect organisms from the biocidal effects of heat and chlorine. Plumbing system design may need to be altered to remove portions not reached by thermal eradication and chlorination and where amplification may continue to occur (e.g., spur pipes).[151] Experience with alternative methods for control and eradication of legionellae in water systems, such as treatment of water with ozone, ultraviolet light, or heavy metal ions, has shown some promising results but is more limited. There is, however, an increasing volume of epidemiologic and laboratory data that suggest that the use of monochloramine as a biocide in municipal water systems is more effective than chlorine in preventing *Legionella* transmission.

Monochloramine is a residual disinfectant that is more stable than chlorine allowing maintenance of active concentrations in larger areas of water distribution systems. Furthermore, it results in reduced production of regulated disinfection by-products such as total trihalomethanes (TTHMs). In 1998, the US Environmental Protection Agency (EPA) issued regulations requiring the reduction in the levels of certain disinfection by-products including TTHMs. Since then, many municipalities are converting to monochloramine as the primary residual disinfectant for their public water distribution systems. In 2004, a survey of municipal water companies in the United States showed that 30% used monochloramine as their residual disinfectant.[168] There are several studies that show a decrease in transmission of *Legionella* when monochloramine is used. In 1999, a case–control study assessed the risk of a hospital having a potable water-associated outbreak of Legionnaires' disease, based on the type of disinfectant used by the municipality.[113] Hospitals that experienced an outbreak were 10 times more likely to be in municipalities that used chlorine as the drinking water disinfectant compared to municipalities that use monochloramine as the disinfectant. These results suggested that approximately 90% of the outbreaks associated with drinking water could have been prevented by a change at the water treatment plant. This study as well as others showed promise for the potential impact of monochloramine in the prevention of *Legionella*. As municipal water companies have switched to monochloramine, there has also been the opportunity to look at the impact of monochloramine prospectively. In Pinellas County, Florida, 96 buildings were tested for *Legionella* before and after the conversion to monochloramine. After the conversion, the percentage of buildings colonized with *Legionella* declined from 19.8 to 6.2%.[140] Results from a similar but larger survey in San Francisco supported this reduction in *Legionella* colonization with monochloramine use.[69] Monochloramine holds promise for the prevention of Legionnaires' disease caused by potable water. Further prospective studies that examine not only colonization but reduction in disease, such as in hospital settings, are needed.

An alternative approach to control is based on periodic, routine culturing of water samples from cooling towers, potable water systems, or other aerosol-producing devices and instituting control measures if legionellae are detected.[4,195] However, this method has not been widely recommended by public health officials because (1) the results of water culture do not necessarily correlate with the potential for transmission; (2) the bacterium is frequently present in water systems without being associated with known cases of disease; (3) interpretation of the results of routine culturing of water is confounded by use of different bacteriologic methods in various laboratories, by variable culture results among sites sampled within a water system, and by fluctuations in the concentration of legionellae isolated from a single site[16,128,130]; and (4) the risk of illness following exposure to a given source is influenced by other factors (e.g., strain virulence, host susceptibility).

The Centers for Disease Control and Prevention (CDC) has published guidelines regarding environmental infection control in health care facilities.[167] They provide no recommendation regarding routine water sampling in hospitals, due to the concerns outlined above, except in the setting of transplants units, where routine water sampling is considered reasonable if it is conducted as part of a comprehensive Legionnaires' disease prevention strategy. In health care settings without transplant units, CDC promotes an approach with primary emphasis on patient surveillance. If one laboratory-confirmed case of hospital-associated Legionnaires' disease or two possible nosocomial, laboratory-confirmed cases occur within a 6-month period, additional measures should be taken including increased retrospective and prospective surveillance for possible cases. The extent to which environmental sampling and remediation occur is dependent on whether there is ongoing transmission of *Legionella* and the links between the epidemiologic and environmental findings.[167] Comparison of isolates from patients and environmental samples, along with appropriate epidemiologic data, allows determination of the source of the disease and appropriate remediation to prevent further cases. Confirmed cases of Legionnaire's disease should be reported to local and state public health authorities.

8.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Erythromycin chemoprophylaxis of immunosuppressed patients at a hospital with a high incidence of nosocomial Legionnaires' disease due to colonization of the hot water distribution system resulted in protection against Legionnaires' disease.[187] However, in view of the generally low attack rate during outbreaks and the potential of eliminating the source of the organism, chemoprophylaxis is seldom indicated except perhaps in settings such as transplant units. An alternative measure in hospitalized patients is to empirically treat with fluoroquinolones immunocompromised patients who develop pneumonia of uncertain etiology.[171]

8.3. Immunization

Although animal models with vaccines for *Legionella* have shown some success, the development of vaccines for humans against legionellosis has not been attempted.

9. Unresolved Issues

9.1. Rapid Diagnostic Tests

The clinical presentation of Legionnaires' disease is similar to that of other types of pneumonia; therefore, accurate, rapid diagnostic tests are essential to ensure appropriate clinical management of patients and early recognition of outbreaks so that prevention strategies may be instituted. Continued development and evaluation of new diagnostic modalities, such as antigen detection tests and polymerase chain reaction, are needed. Tests to detect *Legionella* other than *L. pneumophila* serogroup 1 antigens in urine may become available in the near future.[181] Additional studies are needed to determine whether polymerase chain reaction is as sensitive and specific as culture for identifying *Legionella* in clinical specimens and whether the effect of substances present in sputum that inhibit the assay can be overcome.[60,61]

9.2. Risk Assessment

Although environments capable of supporting the growth of *Legionella*, such as cooling towers and hot water distribution systems, are a daily part of life and the bacterium is frequently present in these systems, transmission resulting in disease occurs relatively infrequently. More information is needed about the specific virulence, host, and environmental factors that increase the risk of transmission. Epidemiological studies in concert with careful environmental investigations can define the risk of Legionnaires' disease attributable to various colonized water systems and aerosol-producing devices. The role of environmental monitoring in risk assessment is yet to be determined, and at present, limited data are available on the association between the concentration of organisms in a water system and the risk of transmission.[16,170] The utility of nonculture methods for

detecting virulent *Legionella* in the environment needs to be further defined.[3,112,124,189] Additionally, the pathogenic potential of *Legionella* and related organisms that are not detected by culture methods designed to detect *Legionella* needs to be assessed.[85,138,159]

9.3. Prevention

Prevention of legionellosis is challenging because of the steps necessary to identify an individual source of transmission, because of the diversity of settings in which the disease occurs, and because of the difficulty in eradicating *Legionella* from aquatic environments. To identify the source of transmission to an individual case, clinicians must diagnose Legionnaires' disease in an individual who presents with community-acquired pneumonia, the case must be reported to public health authorities, and public health authorities must be able to identify the most likely source among the many that are determined to be colonized with *Legionella*. For community-acquired cases, including those associated with travel, the number of potential sources to which an individual is exposed is usually too large to allow definition of a clear epidemiologic link between a specific source and the individual case. Even when the number of potential sites is limited, such as in a hospital, identifying the source of transmission can be challenging because of the lack of sufficient epidemiologic or laboratory data to implicate that source. Finally, remediation of water systems is rarely straightforward and recolonization is common.

CHAPTER 20

Leprosy

Richard I. Frankel and David M. Scollard

1. Introduction

Leprosy (Hansen's disease [HD]) is a chronic infectious disease caused by *Mycobacterium leprae* that primarily affects the skin and peripheral nerves. A number of other organs, including eyes and testicles, may be involved in the infection. HD has been known for over 2000 years and has afflicted millions of people worldwide. In recent times, most patients have been residents of underdeveloped nations. Hansen[1] discovered the etiologic agent over 130 years ago, but it is still not possible to culture this bacterium on solid medium or to propagate it in liquid medium. This has hampered investigation into the pathogenesis of leprosy and there is much about the disease process that we do not understand.

As discussed in Section 8, leprosy may have a variety of clinical presentations, depending on the patient's immune response to the causative organism. The initial clinical form is referred to as indeterminate. The indeterminate lesion is usually single and often heals spontaneously. If the lesion does not resolve spontaneously and the patient is not treated, the disease usually remains localized in patients with a high degree of immunity to *M. leprae* and evolves into tuberculoid disease. If the immune response to *M. leprae* is poor, more extensive (borderline or lepromatous) disease will result. Patients with intermediate degrees of immune response will have intermediate clinical presentations. The terms TT, BT, BB, BL, and LL are commonly used to indicate the polar tuberculoid, borderline tuberculoid, mid-borderline, borderline lepromatous, and polar lepromatous forms of leprosy, respectively. These are described in Section 8. It is also important to be familiar with the WHO classification of patients into paucibacillary (PB) or multibacillary (MB) leprosy. The former is defined as a person with no bacilli detected on slit skin smears (if such an examination is done) or with five or fewer skin lesions. The latter is defined as a person with bacilli detected on slit skin smears or with more than five skin lesions.

While most infectious diseases are characterized by a relatively well-defined incubation period, this is not the case with Hansen's disease. The major reasons for this are lack of historical information to determine the time of infection, lack of a clinical test to determine the time of infection, and difficulty in determining the time of onset of clinical disease. In addition, it is very likely that many, if not most, patients experience a period of latent infection, with disease only appearing when some internal or external factor affects the individual's ability to resist *M. leprae*. This is analogous to human infection with *M. tuberculosis* and probably accounts for those patients reported to have extremely long incubation periods. Rare cases in infants may indicate that the incubation period can be as short as a few weeks, though it is impossible to rule out intrauterine infection in these cases.[2] Most studies suggest that the typical incubation period is from 2 to 10 years, and it is likely that most who do not experience latent infection have an incubation period from 2 to 5 years.[3,4]

As with any uncommon disease, clinicians in the United States often have a low index of suspicion for leprosy and the diagnosis is often made relatively late. The variable immune response and the resulting variable clinical manifestations often present challenges in diagnosis and treatment. An understanding of the clinical manifestations of the infection itself, the clinical manifestations of the immunologic components of the disease, and the problems associated with treatment are essential for proper care of patients. While the factors mentioned above have also hindered progress in control of the disease, nevertheless, great progress has been

made in the last 20–25 years. Much of this improvement has been due to the adoption of multidrug therapy of fixed duration and the World Health Organization (WHO) campaign to eliminate leprosy as a public health problem. Nevertheless, leprosy continues to be a problem in a number of countries and many patients who are no longer counted as cases of leprosy still suffer and require care to manage the sequelae of their infection. In addition, while much progress has been made, some patients continue to suffer from the stigma associated with leprosy. Hence many people prefer to use an alternate term such as Hansen's disease or hanseniasis.

2. Historical Background

It is uncertain just where and when leprosy first appeared and whether biblical "leprosy" was in fact leprosy as we know it today. However, the opinion of some authorities[5] has been that it started in the Indian subcontinent before 600 BC and then spread initially to Asia and Africa and later to Europe. Geographic spread has been associated with the movement of people associated with the spread of religion and the movement of people associated with military campaigns. A recent study, utilizing genetic markers for strains of *M. leprae*, suggests that the disease originated in East Africa or the Middle East (the authors use the term "Near East") and spread from there to Europe and North Africa.[6] The incidence of the disease in Europe probably peaked in the Middle Ages and then gradually declined, virtually disappearing in most of Europe, though it is still found in some countries that border the Mediterranean Sea. The reasons for this disappearance are uncertain, but it is very likely that leprosy, like tuberculosis, is significantly impacted by socioeconomic conditions and that improvement in hygiene, housing, and nutrition played a major role in the waning of the epidemic.[5]

Leprosy was probably introduced into the Americas by the Spanish and subsequently other colonialists and also by means of the slave trade. The first definite reference to the disease in the United States was in Florida[7] in 1758. In the 1760s, cases occurred among the French near the mouth of the Mississippi River. In 1785, a hospital was established in New Orleans, Louisiana, for the treatment of leprosy patients, and over 100 years later (1894), this facility was moved to a location near the village of Carville, becoming the Louisiana Leper Home. Patients from many states began seeking care there, leading the federal government to acquire the institution in 1921. It was initially called the National Leprosarium, later the Gillis W. Long Hansen's Disease Center (GWLHDC) and subsequently the National Hansen's Disease Program (NHDP). The residential treatment program of the center ended following federal legislation passed in 1998.[8] In addition, outpatient treatment, rehabilitation, training, and research moved to Baton Rouge, Louisiana. Each year, a few US-born individuals are diagnosed with Hansen's disease. Most patients in the United States acquire their infection in other countries and transmission within the United States is rare. Cases continue to occur in immigrants from countries where the disease is still prevalent.[9] Hawai'i, California, Texas, Louisiana, Florida, and the New York City area report the most cases. In the 19th century, there were many cases in Scandinavian immigrants residing in and around Minnesota, but this focus has now completely disappeared. A settlement for patients in Hawai'i was the result of quarantine on the island of Moloka'i, which began in the 19th century. No new patients have been sent to the settlement, now called Kalaupapa, since 1969. Not all of the patients eligible to reside there do so, and some reside there on a part-time basis. There were 25 patients eligible to live there as of October 13, 2008, with the number steadily decreasing due to deaths in a population that is now elderly. Another US leprosy settlement on Penikese Island, Massachusetts, closed in 1921.

Significant milestones in the history of leprosy include the discovery by Hansen[1] of *M. leprae* as the causative agent of this disease in 1873, the introduction of sulfone therapy in 1941,[10] the development of the mouse footpad technique for growing the bacillus in 1960,[11] recognition of the immunologic basis of the spectrum of pathologic changes in leprosy in 1964,[12] the discovery that the bacillus grows readily in the armadillo in 1971,[13] the development of fixed duration antimicrobial therapy in 1981,[14] and the cloning of the *M. leprae* genome in 2001.[15]

3. Methodology

3.1. Sources of Data

3.1.1. Sources of Mortality Data. Leprosy is rarely a fatal disease and thus mortality data are not useful in understanding the disease. Fatalities related to leprosy almost always result from secondary bacterial infection of wounds related to dysfunction of sensory and, to a lesser extent, motor nerves. Rarely, individuals may die from renal dysfunction related to a type 2 Hansen's disease immunologic reaction (Gell–Coombs type 4) or to renal amyloidosis or from an adverse reaction to medication. Prior to the availability of effective antimicrobial therapy, laryngeal involvement was fatal for some patients.

3.1.2. Sources of Morbidity Data. Although many countries list leprosy as a reportable disease, existing

morbidity data on leprosy are often unreliable. There are still varying degrees of stigma attached to the disease in most countries, so that some patients may try to either conceal the diagnosis or seek the care of physicians who will not report it. In addition, the disease has traditionally been difficult to diagnose and cases are often missed. As the disease has become less common, fewer health care workers are familiar with it and thus the diagnosis may be missed more often. The World Health Organization (WHO) collects data and publishes annual summaries and periodic updates.[16] WHO reports registered cases at the beginning of the year and the number of cases detected during the preceding year. There are two important caveats. First, WHO defines a registered case as a person with leprosy who has not completed a full course of treatment. Patients who have residual disability or who have immunologic complications but are not felt to require antimicrobial therapy are not included in WHO prevalence data. Thus, these data underestimate both the burden of suffering and the burden to the health care system. Second, although case detection rate is used to approximate the incidence rate, the factors listed above result in an underestimation of the true incidence rate in many countries.

In the United States, leprosy is a reportable disease in most states and it seems likely that almost all cases are reported to the national registry at the National Hansen's Disease Program (NHDP) and to the Centers for Disease Control and Prevention (CDC). Cases are reported on a weekly basis by CDC in the *Morbidity and Mortality Weekly Report* under "Provisional cases of infrequently reported notifiable diseases (<1,000 cases reported during the preceding year) – United States"[17] and annually by NHDP electronically.[18]

3.2. Surveys

Surveys to detect new cases of leprosy and to assess prevalence have primarily been done by clinical examination of defined populations. The most common of these have been household contact examinations, but community surveys, school surveys, and examination of special groups have been productive in certain circumstances.[19] In actual practice, most cases are found by voluntary reporting or referral by medical personnel. In highly developed countries where the disease is rare, examination of household and other very close contacts is the only kind of survey that has any practical value.

There has been considerable confusion about the lepromin skin test. Although it is no longer useful clinically, we include this discussion because there are frequent references to it in the literature, primarily the older literature. Some have erroneously viewed it as analogous to the tuberculin skin test for tuberculosis. In fact, the lepromin skin test is not useful as a screening test for leprosy. The test measures the person's cell-mediated immune response to killed *M. leprae*. It has a very low sensitivity in leprosy patients at the lepromatous end of the spectrum, in whom *M. leprae*-specific cell-mediated immunity (CMI) is uniformly low or absent. It has a very low specificity in leprosy patients at the tuberculoid end of the spectrum, as there is cross-reaction to infection with other mycobacteria. Thus, the lepromin test is not useful for detecting leprosy cases in populations or in individuals. It is also no longer necessary or useful for clinical classification of leprosy. It is presently only used in research studies. For historical purposes, it is worth noting that lepromin was initially prepared from tissue of human patients with leprosy. Since the development of the armadillo model, virtually all lepromin is now prepared from armadillo tissue and is known as lepromin A. A purified preparation known as Dharmendra lepromin has been used in India. For lepromin testing, a single 0.1-ml dose of the preparation was injected intracutaneously, and readings were taken at 48 hours (Fernandez reaction) and at 3–4 weeks (Mitsuda reaction). There was some correlation of the Mitsuda reaction with clinical findings but, as noted, the test is no longer used. Other tests of the immunologic response to *M. leprae*, including tests of lymphocyte response to *M. leprae* antigens and antibody assays, have been used in surveys. The tests of cell-mediated immune responsiveness have the same limitations as the lepromin test and are not useful in the management of patients.

Of the various antibody tests that have been developed, the one that has been most widely studied is detection of antibody produced in response to phenolic glycolipid-I (PGL-I). This glycolipid is found in the capsule of *M. leprae*. It contains a trisaccharide moiety that has not been found in any other bacterium. Thus, antibodies to PGL-I should be specific for infection with *M. leprae*. Antibodies to PGL-I are usually present in patients with generalized forms of leprosy, i.e., BL and LL disease. Diagnosis in this group of patients can be readily made by standard clinical tests, however. Antibodies are sometimes found in patients with localized forms of leprosy, i.e., TT and BT disease, but the sensitivity of the test is low if used for diagnostic purposes. For example, one study found that antibodies were present in 93.1% of patients with a bacterial index of 4.0–5.0 but in no patients with bacterial index of 0–1.9.[20] Likewise antibodies are found more often in contacts of patients with leprosy than in the general population, but there is limited correlation between finding antibodies in an asymptomatic individual and the likelihood of that individual subsequently developing clinical leprosy.[21] Thus, detection of anti-PGL-I antibodies is not used for clinical diagnosis but only in research studies.

The most recent development in this area is the use of the polymerase chain reaction (PCR) as a direct test for

the presence of *M. leprae* DNA. A study[22] of nasal swabs taken from patients in the Philippines showed that the swabs were PCR positive for *M. leprae* in 55% of untreated leprosy patients, in 19% of persons who worked with leprosy patients daily, and in 12% of persons who worked in the same area but had no direct contact with leprosy patients. In a study in Indonesia, *M. leprae* was detected by PCR in 7.8% of nasal swabs among all subjects in a population-based study of two villages with a high prevalence of leprosy, with no correlation between the PCR results and serologic testing for IgM antibodies to PGL-I.[23] While these studies have been valuable in demonstrating frequent nasal carriage of *M. leprae* in asymptomatic individuals, they have not been useful in terms of screening for disease and are not likely to be used in this manner in the future.

3.3. Laboratory Diagnosis

In developed countries, the only diagnostic test for leprosy is a skin biopsy. This is generally a punch biopsy. There are three caveats with regard to obtaining and processing the biopsy. First, for annular and plaque-type lesions, the biopsy must be obtained from the margin of the lesion rather than the center. The central clearing that is observed clinically may be accompanied by loss of the typical histopathologic features. Second, the biopsy should be full thickness, down to the subcutaneous fat, as sometimes the diagnostic findings are localized to the deep dermis. Finally, the Ziehl–Neelsen stain should not be used when looking for *M. leprae*. This bacterium is less acid-fast than *M. tuberculosis* and thus may not be seen with a Ziehl–Neelsen stain. Instead, a modification of the Ziehl–Neelsen stain is necessary. The Fite–Faraco method, which enhances the weak acid-fastness of *M. leprae*, is most often used. The stain is commonly called the Fite stain.

A major recent addition to laboratory diagnostic capabilities for leprosy is the development of the polymerase chain reaction (PCR) assay for *M. leprae* DNA.[24] This test can be performed on formalin-fixed, paraffin-embedded tissue as long as exposure to formalin is not greater than 24 hours. The test is frequently negative when few bacilli are present. It is therefore used to determine which mycobacterium is present when organisms have been identified in Fite–Faraco-stained sections and it does not replace the standard microscopic examination of Fite–Faraco-stained sections.[25]

3.3.1. Isolation and Identification of Organism. Unlike most pathogenic microorganisms, there is no diagnostic culture method for *M. leprae*, although PCR identification of *M. leprae* DNA is possible, as noted above. In the past, slit skin smears were important in diagnosis and contributed information that was helpful in making therapeutic decisions. Skin smears involved obtaining fluid and some tissue from the dermis and examining it for acid-fast bacilli. In highly developed countries with a low incidence of leprosy, skin biopsies are virtually always done for diagnosis. Skin smears are therefore seldom useful in these places. While still of some use in situations where skin biopsies are not routinely done, the World Health Organization no longer recommends them for routine use but relies instead on its clinical classification system. Aside from the diminished clinical value of the smears, there has been a problem with reproducibility of results, which has also reduced their clinical utility.

For historical purposes and understanding of older literature, it is useful to know that slit skin smear results were quantified by reporting the number of bacilli seen using a semilogarithmic scale called the bacterial index or BI. The results ranged from zero to six. In addition, the percentage of acid-fast bacilli that were intact was reported as the morphologic index or MI. Of particular interest is the fact that the MI was usually 1–5% and virtually never over 20%, even in the untreated patient with diffuse lepromatous leprosy.

As initially reported by Shepard in 1960,[11] *M. leprae* will grow in the mouse footpad. This discovery was a monumental breakthrough in terms of leprosy research and in assessing and demonstrating the efficacy of antimicrobial agents. It was one of the key scientific elements that led to the end of isolation of leprosy patients in the late 1960s. Growth in mouse footpads has not had and does not have a role in terms of diagnosis of leprosy.

Although *M. leprae* cannot be cultured in vitro, there are now several studies reporting limited metabolism in cell-free in vitro radiorespirometric systems. The method most studied is a system that measures $^{14}CO_2$ evolution from ^{14}C-labeled palmitic acid, such as the BACTEC and Buddemeyer systems, utilizing nude-mouse-derived *M. leprae*. These techniques have been used to screen potential antileprosy drugs and are a significant advance from using animal models.[26] Recent studies show that radiorespirometry may also be utilized to assess viability of *M. leprae* in biopsies taken from patients during treatment and could potentially be used to quantify response to antibacterial treatment.[27] Again, in vitro culture has no role in the diagnosis of leprosy.

3.3.2. Serological and Immunological Tests. Most aspects of serological and immunological tests have been reviewed in Section 3.2 above. For practical purposes, such tests are not useful in the diagnosis of leprosy. There have been numerous studies of PCR as a possible method of diagnosis. In general, most patients in whom AFB are demonstrated in routine biopsies also are positive for *M. leprae* on PCR testing. In these patients, PCR does not facilitate the

diagnosis. In those biopsies in which AFB are rare or negative, where only the presence of granulomatous infiltrate and involvement of peripheral nerves suggest the diagnosis of leprosy, only 50–60% are positive for *M. leprae* by PCR. When positive, PCR can consistently distinguish *M. leprae* from other mycobacterial species.[25,28] This is useful in those few situations where there may be diagnostic confusion between leprosy and infection due to so-called atypical mycobacteria. PCR for *M. leprae* is highly specific and sensitive and offers a new approach to identifying *M. leprae* under clinical conditions.[29] It seems unlikely, however, that this test will play a significant role in most countries.

4. Biological Characteristics of the Organism

Although *M. leprae* organisms cannot regularly be isolated and positively identified from all patients with leprosy but only from patients with high bacterial counts, and the Henle–Koch postulates have therefore not been and likely will not be fulfilled, almost all believe that *M. leprae* is the causative agent of leprosy. *M. leprae* was first described in 1873 and was the first bacterium to be identified as a cause of human disease. However, with the exception of the limited growth mentioned above, it has not been propagated in any artificial medium and has never been grown on solid medium. Thus the usual methods for studying bacteria have not been applicable. Consequently, less is known about this bacterium than most other bacteria of medical importance.

M. leprae is a gram-positive acid-fast bacillus, 0.3–0.4μm × 2–7μm. It is an obligate intracellular parasite. It is the only bacterial species with a special predilection for peripheral nerves and specifically for Schwann cells. On skin smears or biopsy sections, the bacilli are often clustered in oval formations called globi. Over 90% of the bacilli from a typical new patient stain irregularly and appear to be nonviable in mouse footpad studies.[30] With effective chemotherapy, all bacilli become granular and disintegrate. Although the disintegrating bacilli appear to slowly clear with treatment, this clearing may be due in part to a loss of acid-fastness by the bacillary remnants rather than to actual disappearance of the bacilli. Staining with the Gomori methenamine silver technique has demonstrated bacilli in some biopsy sections that had shown none on a Fite–Faraco stain.[31]

M. leprae will survive in soil for up to 33 days[32] and in dried secretions for up to 9 days in a hot, humid climate.[33] At the temperature of wet ice, they may survive 2 weeks or more, while heating at 45°C for 1 hour[34] or freezing[35] kills them. In experimental systems in vitro, these bacilli die much more rapidly at 37°C than at 33°C. The antigenic activity of cell wall antigens persists at temperatures of over 200°C.[36] In the mouse footpad, maximum growth occurs at an average footpad temperature in the 27–30°C range.[37] This corresponds to its growth pattern in humans where the highest bacterial counts occur in the cooler areas of the body such as the skin, extremities, and the anterior portion of the eye. In the mouse footpad, there appear to be "fast"- and "slow"-growing strains, but it is not clear if these characteristics have any bearing on human disease. A number of specific *M. leprae* antigens have been identified using monoclonal antibodies. The most thoroughly investigated from a clinical point of view is PGL-I, discussed above.[21] There are also many non-specific *M. leprae* antigens.

The large number of relatively tissue-free bacilli obtainable from armadillos has made it possible to prepare *M. leprae* DNA libraries in *Escherichia coli* vectors and to sequence the entire genome,[15] enabling application of some of the techniques of molecular biology to the study of this organism. When its genome is compared to its close relative, *M. tuberculosis*, it is apparent that *M. leprae* has undergone an extreme case of reductive evolution.[38] This is reflected by the smaller genome (3.3 Mb for *M. leprae* versus 4.4 Mb for *M. tuberculosis*) and a major reduction in G+C content (58% for *M. leprae* versus 66% for *M. tuberculosis*). *M. leprae's* annotated genome contains only 1,614 open reading frames (ORF) encoding potentially functional proteins, compared to 3,993 ORF in *M. tuberculosis*. In addition, the *M. leprae* genome contains 1,133 "pseudogenes" (inactivated genes whose function has been lost through mutation), compared to only 6 pseudogenes in *M. tuberculosis*.[39] Complementing the work on sequencing the genome of *M. leprae* is work on sequencing the genome of *Dasypus novemcinctus*, the nine-banded armadillo. This will almost certainly yield important information regarding the unique susceptibility of this animal to lepromatous leprosy. Adams and coworkers recently reported success in expressing armadillo interleukin-2 in *E. coli*.[40]

To identify genes transcribed during infection, gene transcripts from *M. leprae* growing in athymic nude mice have been studied using an *M. tuberculosis* microarray.[41] The transcripts detected thus far indicate that *M. leprae* actively catabolizes fatty acids for energy. In addition, the bacillus produces a wide range of secretory proteins, utilizes the limited array of sigma factors available (a sigma factor is a protein component of RNA polymerase that determines the specific site on DNA where transcription begins), produces several proteins involved in the transport, storage, and regulation of iron, and transcribes several genes associated with virulence in *M. tuberculosis*.[42]

The proteome of *M. leprae* has been evaluated using subcellular fractionation of *M. leprae*, combined with

immunologic screening (using serum and T-cells from leprosy patients and contacts) and examination of purified proteins by micro-sequencing and mass spectrometry. Proteins have been identified from major cellular compartments including cytosolic, membrane, and cell wall. The results have been summarized.[43] Analysis indicates that *M. leprae* has lost many metabolic pathways together with their regulatory circuits, particularly those pathways with catabolic potential.[38] Secreted proteins of *M. leprae*, previously not accessible in this non-cultivable organism, can now also be studied using molecular techniques and bioinformatics analysis. The results thus far indicate that *M. leprae* does have the potential to produce a variety of secreted proteins,[41] but most of these have yet to be studied regarding their role in pathogenesis, value for diagnostic testing, or potential use as immunostimulating agents for therapeutic or preventive use.

5. Descriptive Epidemiology

As noted in Section 3.2, most of the current epidemiologic data come from the World Health Organization. US data come from the Centers for Disease Control and Prevention and the National Hansen's Disease Program.

5.1. Prevalence and Incidence

There have been dramatic changes in the global number and distribution of cases of Hansen's disease in the past two decades. The terms "incidence" and "prevalence", as applied to leprosy, refer to the number of new cases registered and the total number of cases registered, respectively. As a result, they are subject not only to changes in the occurrence of the disease in the population studied but also to marked change as a result of operational factors affecting the specific registry. In considering these data, then, the reader must be aware of certain factors. First, incidence often varies widely within a given country and sometimes even within smaller regions such as provinces, states, or smaller sectors. In addition, leprosy, as with many diseases and especially with uncommon and/or potentially stigmatizing diseases, is underdiagnosed and underreported. Thus, case detection rate is reported rather than incidence rate. Third, WHO data include only those persons diagnosed with leprosy who have not completed a course of antimicrobial therapy. They do not include patients who have completed antimicrobial therapy but have residual physical and/or emotional disability. This group of patients may require significant health care resources for treatment, education, rehabilitation, and psychosocial support.

Global leprosy prevalence had been increasing progressively through the 1970s and early 1980s. The number of registered cases was approximately 2.83 million in 1966 with an estimated prevalence of 10.8 million. There were 3.6 million registered cases in 1976 with an estimated prevalence of 10.6 million, and 5.37 million registered cases in 1985 with an estimated prevalence of 10–12 million. While some of this increase was likely due to increased case finding activities, there was clearly a true increase in cases. This trend, along with concern about increasing resistance of *M. leprae* to dapsone, led a WHO study group convened in 1981 to recommend in 1982[14] that all patients be treated with defined-duration multidrug therapy. The subsequent implementation of this recommendation has led to dramatic changes in prevalence. The number of registered cases fell to 1.67 million with an estimated prevalence of 2.43 million in 1994.[44] At the beginning of 1999, there were 731,000 registered cases.[45] At the beginning of 2004, there were 458,000 registered cases.[46] This number had fallen to 225,000 at the beginning of 2007.[16]

In 1990, the World Health Assembly recommended an international effort to eliminate leprosy as a public health problem by the year 2000.[47] The assembly defined elimination as a prevalence rate below 1 case per 10,000 population in every country and in the major subunits of highly endemic countries. By the beginning of 2005, all but nine countries had achieved the elimination target.[16] (There were 122 such countries in 1985.) These nine were Angola, Brazil, Central African Republic, Democratic Republic of the Congo, India, Madagascar, Mozambique, Nepal, and the United Republic of Tanzania. These nine countries, with a registered prevalence of 212,000 at the beginning of 2005, accounted for about 74% of all of the registered cases. India alone accounted for about 70% of the cases among the nine countries or 52% of the global total of registered cases. By the beginning of 2007, only Brazil, the Democratic Republic of the Congo, Mozambique, and Nepal had not yet achieved the elimination goal.[48] As the number of countries failing to meet the elimination target has diminished, WHO has moved from a strategy of targeting every country to one utilizing a Special Action Project for the Elimination of Leprosy (SAPEL) in each targeted country or specified geographic region.[49] Started in 1995, these programs focus on areas with high leprosy caseloads and/or inadequate leprosy services with the primary goal of improving delivery of multidrug therapy (MDT). Also in 1995, leprosy elimination campaigns (LECs) were established in selected countries, focusing on improving case detection.[49] New cases are, of course, then treated with MDT.[50]

While the prevalence was falling, there was concern about the failure of the case detection rate to decline. For

example, there were 584,412 new cases reported in 1991[51] and 653,354 new cases reported in 1992.[52] This number fell to 590,933 cases in 1993[44] but rose during the last half of the 1990s to a peak of 804,449 in 1998.[45] Initially it was assumed that the increase was due to increased case detection, better reporting, more patients seeking treatment, and other operational issues. Over time, however, more concern was directed toward such possible factors as the role of the person colonized with *M. leprae* but without clinical signs of leprosy and the role of non-human sources of infection. More recent data suggest that MDT and the associated programs established by WHO have in fact reduced the occurrence of new cases. The rate has fallen progressively to 514,718 cases in 2003,[46] 407,791 cases in 2004,[16] 299,036 cases in 2005, and 259,017 cases in 2007.[48] The importance of local epidemiology is emphasized by the fact that the decrease has been marked in the South-East Asian region of WHO and modest in the East Mediterranean and Western Pacific regions but has not been observed in the African or American regions. The fact that the South-East Asian region had almost 88% of the newly detected cases in 2001 and about 73% of the cases in 2004 demonstrates that improvement in this region will have a major global impact and that improvement in leprosy control is not evenly distributed.

The most recent US demographic data are for the calendar year 2004.[9] Notable findings include the registration of around 100–140 new cases each year since 1997. California, Texas, Hawai'i, and New York reported the most cases, 91 (70%) of the 131 total cases in 2004. About two-thirds of the cases were male, consistent with previous reports in this country. A total of 25 of the 131 cases (19%) were individuals born in the United States, the most of any country. The countries with the next greatest number of cases were Mexico (24), Micronesia <sic> (15), Brazil (12), and the Philippines (10). Only Texas (10), Louisiana (4), and Mississippi (2) had more than one US-born case. Nine states reported one US-born case each during that year. About one-third of the US-born cases were Hispanic, white ethnicity and one-third Asian or Pacific Islander, though the author of the report notes that some of the latter cases should have been reported in 2003. A total of 20 cases (15%) were white, not of Hispanic origin, but 16 of the 20 white, not of Hispanic origin cases were endemic, accounting for 64% of the endemic cases. It is difficult to get exact data for the United States, as registered cases are never removed from the national registry. Almost 12,000 cases had been registered as of October 2005. As of that date, there were 3,604 patients on the US registry who were currently receiving care, 2,146 of whom (60%) were receiving MDT. The US Centers for Disease Control and Prevention reports cases reported by states on an annual basis. The disease is not reportable in all states. The latest data for 2006 were published at the beginning of 2007.[17]

5.2. Epidemic Behavior and Contagiousness

Leprosy is often referred to as an infection with a low degree of contagiousness. In addition, statements such as "disease transmission takes place only after years of exposure" still appear in the literature. More recent data, primarily serologic data with support from PCR studies, demonstrate that *M. leprae* has a relatively high infectivity but a low virulence for most individuals.[53] Most infected individuals never have any evidence of disease. Were there a skin test comparable to the tuberculin skin test for diagnosis of latent infection, it is likely that the concept of infectiousness in leprosy would have evolved differently.

Epidemics in the usual sense of the word are rare with leprosy. While the spread of leprosy throughout Europe in the Middle Ages has been referred to as an epidemic,[5] many of the cases were probably not leprosy, the spread was gradual over a period of many years, and there is very little accurate information about it. The Nauru epidemic in the 1920s is the best-documented occurrence of a true leprosy epidemic.[54] Leprosy was reportedly introduced into this Central Pacific island by a woman who arrived there from the Gilbert Islands (now Kiribati) in 1911 or 1912. In 1920, the first case appeared among the native population, and by 1924, there were 284 cases in the population of about 1,200 individuals. Case finding was very active, with monthly examination of everyone on the island. By 1929, 438 cases had been found, and apparently the incidence gradually diminished thereafter. Thus, at the peak of the epidemic, about 35% of the population had been diagnosed as having leprosy. At the same time, many patients were noted to have cleared their infection and were then removed from the registry, so that 119 patients were discharged in 1928 alone. At the end of 1941, there were 133 patients on the island, 41 in the isolation facility and 92 being treated as outpatients. The Japanese controlled Nauru during much of World War II. They reportedly rounded up the remaining 41 patients who were confined in the isolation facility, sent them to sea in a ship and then sank the ship. Detailed data from 1950 show 12 cases in segregation and 56 treated as outpatients with a prevalence rate of 4.3%. Over 90% of the cases on Nauru were reportedly of the tuberculoid type, and deformities were uncommon. On the basis of the findings in Nauru, New Guinea, and elsewhere, Leiker[55] noted that when leprosy is introduced into a population which has not previously encountered *M. leprae*, what is essentially an "epidemic" of tuberculoid leprosy occurs, the disease spreads rapidly, there are no foci of infection,

i.e., particular villages and families with a higher incidence than others, and adults and children are equally susceptible. In old endemic areas, however, there is more lepromatous disease than in the newly infected population, a higher proportion of the cases are among children and young adults, the disease spreads slowly, and there are foci of infection. It is evident that the pattern of leprosy in Nauru (an extreme and unprecedented example) and in other newly infected populations does indeed fit Leiker's postulates. However, it is more difficult to characterize the situation in most countries on the basis of such a hypothesis, particularly since nearly all data are now reported to WHO in terms of PB and MB or unclassified disease. Nonetheless, WHO does report a rise in the proportion of MB cases in Africa, but PB leprosy has become more frequent in the Americas and Asia, and some districts in India report up to 70% of cases presenting with a single lesion.[44] The reasons for this are uncertain. In the most recent report from the United States,[9] 52% of cases were classified as lepromatous, 10% as borderline, and 33% as tuberculoid or indeterminate.

5.3. Geographic Distribution

Leprosy is often called a tropical disease. It is true that currently leprosy is virtually limited to tropical and subtropical regions. If one recalls that Hansen and others studied leprosy because it was a major health concern in Norway and one notes the spread of disease in Europe in the Middle Ages, it is clear that leprosy is not intrinsically a tropical disease, in the sense that trypanosomiasis spread by tsetse flies is tropical because the flies are found only in the tropics. As mentioned above, leprosy is distributed largely according to socioeconomic factors. Most of the underdeveloped countries where leprosy persists as a problem are in tropical or subtropical regions. Based on this, leprosy is found in these regions, but climate and latitude have nothing to do with this distribution.

5.4. Temporal Distribution

There is no significant variation in occurrence with the seasons. The association with tropical climates as a marker of countries with less developed economies has been mentioned above. The previously cited US report for 2004[9] noted a disproportionate number of cases reported in the first seven months of the year. Factors which may influence this pattern include contact tracing, increased vigilance for and awareness of Hansen's disease once a case has been diagnosed, clusters of cases in immigrants, and the vagaries of state reporting systems.

5.5. Age

While leprosy may occur in persons of virtually any age, there are some age-related factors that influence the incidence. Leprosy is uncommon in children below 2 years of age,[56] though occasional cases below the age of 6 months have been reported.[57] A significant number of cases below 5 years of age will be found in countries with a high or very high prevalence, indicating active transmission of the disease, and prevalence rates rise up to age 14, reaching values as high as and occasionally higher than those for the general population. Guinto[58] stated that "it is a fact that children are much more susceptible than adults", but Newell[59] believed that statistics in this regard could be equally well interpreted as indicating only that children have more opportunity for exposure. Findings in Goa and from some series in India and other countries demonstrate the great variations seen not only from country to country but also within the same country.[60,61] Generally speaking, the median age at onset is somewhere between 20 and 30 years. The most recent data from the United States[9] show that about 35% of the cases are in the age group of 25–39 years and 29% in the age group of 40–64 years at the time of diagnosis, with the oldest being 82 years. The mean age was 40.6 years and the median 37.5 years. The median age for the US-born cases was older at 56.8 years.

5.6. Sex

Sex ratios are generally 1:1 for children, but for adults the disease is usually more prevalent among males by a ratio of about 1.5–2:1, except in Africa where females predominate in some populations.[62] Cumulative US data through 2003 show a male:female ratio of 1.7:1.[63] The reason(s) for this predominance of adult males is unknown. Possible factors include genetic susceptibility and greater exposure outside of the household setting in most cultures. The US data, of course, are subject to possible gender differences in immigration.

5.7. Race

Although there are wide variations in incidence and prevalence and in the way the disease manifests itself throughout the world, there are no data that indicate any special race-related susceptibility or resistance. The previously mentioned variation in prevalence within countries and even within governmental jurisdictions within countries suggests that racial susceptibility is not a significant factor in the epidemiology of leprosy. Genetic considerations are discussed under Section 5.11 below.

5.8. Occupation

There is no particular relationship between occupation and the occurrence of leprosy. Some studies[64] have found an increased incidence of leprosy among missionaries working with leprosy patients; however, the prevalence was well below that in the population they were serving and was "increased" only over the prevalence in their homelands. In one study,[65] native hospital workers actually had less chance of contracting the disease than their counterparts in other occupations, and no cases have occurred among the staff at Carville. In this regard, the experience in Hawai'i is particularly interesting. Father Damien went to Moloka'i to care for the people with leprosy who had been exiled there. He arrived in 1873, the same year that Hansen first identified the bacillus that we now call *M. leprae*. Damien reportedly first noted a skin lesion in 1876 and apparently developed other symptoms in the 1880s. He was diagnosed with leprosy in 1885.[66] He died in 1889. He is the only health care worker in Hawai'i known to have contracted leprosy. One of us (RIF) has heard an anecdotal report of a second case but has never seen any confirmation of this.

5.9. Occurrence in Different Settings

The incidence of leprosy has generally been higher in family members where there is one or more cases in the family than in families with no cases, but considerable variation exists. Guinto[58] noted that, in a retrospective study done in the Philippines in 1935, the risk of contracting leprosy was eight times greater in family contacts of lepromatous patients than in the general population. In a follow-up prospective study (1935–1950), however, the risk was about five times, rather than eight times, greater. A study by Kluth[67] in Texas found that 2.6% of 1,522 household contacts of lepromatous patients developed leprosy. On the other hand, after a review of several other series, mostly foreign ones, Filice and Fraser[68] concluded that the long-term risk was such that about 10% of the household contacts of lepromatous patients would ultimately develop the disease. More recent studies have yielded similar data.[69] In all these studies, exposure to tuberculoid and probably indeterminate disease had an extremely small effect, i.e., the incidence of leprosy in families of tuberculoid and indeterminate cases was not significantly higher than in the general population. In US studies, the risks of exposed adults and children have been about the same, but in other countries, the risk for children is considerably higher.[68] The chance of a patient with leprosy infecting their spouse has also been evaluated[70] and seems to be about 5%. Institutional exposure can occasionally lead to very high rates. Of 2000 children born in or admitted to Culion Leprosarium in the Philippines in the 1930s without any sign of leprosy, 23% later developed the disease.[70] A large majority of these children experienced spontaneous healing of their lesions.[70] One must keep in mind that these studies all focus on contact with patients who had not been treated. As demonstrated in the seminal study by Worth[71] which was instrumental in ending quarantine for patients with leprosy, the risk in family members of a patient on effective therapy for leprosy is no greater than the risk of the general population in that community.

There was a report of 240 cases known to have occurred among US military veterans from 1940 through 1968.[72] The authors found that 46 of the cases were considered to have service-connected leprosy from exposure outside the United States during the course of their military duty. As the prevalence rate in the United States and globally has fallen since then, almost all new cases in US-born veterans, as in the rest of the population, would be expected to be acquired outside of the country.

The situation with regard to patients infected with the human immunodeficiency virus (HIV) is more complex. Since the initial case report,[73] there have been multiple case reports and a number of population-based studies[74,75] of the occurrence of leprosy in individuals with HIV infection. Overall, HIV infection does not seem to exert a significant influence on either the incidence or the clinical manifestations of leprosy, though not all studies are in agreement.[76] One possible exception to the lack of interaction between HIV and leprosy is the relatively recently observed immune reconstitution inflammatory syndrome in patients with leprosy and HIV who are treated with so-called highly active antiretroviral therapy (HAART) and respond to this treatment.[77,78] Clinically, this is probably a type 1 reaction, though the reaction may be more severe and more difficult to manage than the typical type 1 reaction not associated with HIV and its treatment.

5.10. Socioeconomic Factors

Leprosy today occurs mostly among the poor in underdeveloped countries. Why this is so is uncertain; however, crowded living conditions, poor diet, inadequate medical care, and improper sanitation may all play a role. As noted earlier, the incidence and prevalence of tuberculosis declined in many countries prior to the availability of antimicrobial chemotherapy. This was almost certainly due to better living conditions and better overall health. The same has occurred with leprosy and is consistent with the concept that the primary route of transmission of *M. leprae* is the respiratory route, as discussed in detail in Section 6. Good housing

conditions and extended schooling, for example, reduced the risk of leprosy in Malawi.[79]

5.11. Other Factors

Observations of familial clusters of leprosy cases, wide variation in prevalence and type of leprosy within a given population, high concordance rates of leprosy in identical twins,[80] and the persistence of anergy to *M. leprae* in patients with inactive lepromatous leprosy all suggested the existence of a genetic predisposition to leprosy.[81] Based on multiple studies in recent years, there is abundant evidence that genetics is critically important in determining the manifestations of leprosy. There is now a convincing body of evidence that indicates that different genes influence the human immune response to *M. leprae*, reviewed by Scollard et al.[42] These genes operate at two levels. The first level influences the overall susceptibility and resistance to this bacterium through its influence on "innate" resistance, mediated by cells of the monocyte lineage. If this innate resistance is insufficient to prevent infection and *M. leprae* becomes established in the individual, the second level of genetic control becomes important. This influences the degree of specific cellular immunity and delayed hypersensitivity generated by the infected individual. Such specific or acquired immunity is mediated primarily through the function of T lymphocytes, in cooperation with antigen-presenting cells. The association of genes with both innate and acquired immunity has recently been reviewed by Marquet and Schurr,[82] and genetic defects in different components of the type 1 cytokine pathway that affect human resistance to mycobacteria have been reviewed by van de Vosse et al.[83]

This recent demonstration of a marked genetic influence is not surprising, due to the accumulating evidence that genetic susceptibility is important in a number of infectious diseases.[84] This genetic influence likely impacts both whether or not the individual will develop any clinical manifestations of leprosy and whether the individual will develop disease toward the tuberculoid or the lepromatous end of the spectrum, although findings differ in various studies.[85,86,87] While mouse susceptibility to mycobacterial infection has been clearly linked to a specific protein, natural resistance-associated macrophage protein 1 (NRAMP1),[84] no association with NRAMP1 genotype and leprosy was found in one study.[88] This study did demonstrate an association with vitamin D receptor genotype. Another study suggests that genetic control of cytokine production may be the key.[89] This is an important and complex field and additional findings will probably contribute greatly to our understanding of the epidemiology of leprosy.

6. Mechanisms and Routes of Transmission

Over the years, the oldest and most prevalent opinion was that the major route by which *M. leprae* gained access to the human host was through the skin. This could have resulted from direct skin contact with an infectious case or from introduction of the organism onto the skin by a fomite. Evidence cited[58] to support the theory of infection by direct skin contact includes the appearance of the first leprosy lesion in children at the sites most touched by their infected mothers, accidental inoculation by tattooing or at surgery, and inoculation via thorn penetration in animal models.[90] This evidence actually provides relatively little support for transmission via the skin. While the bacillus might occasionally be inoculated via injuries that pierce the skin, a history of such an injury is rare and the literature contains a number of studies showing that the site of the first lesion in children is not related to the extent to which an area is touched.[91] Furthermore, over 50% of cases in regions of low to moderate endemicity give no history of contact with a leprosy case.[92] Thus, "prolonged" or "intimate" contact in these instances seems unlikely. While it is possible that fomites have contact with *M. leprae* in soil or peat and transfer it to skin of a person, there is no clinical evidence to support this route of acquisition. In addition, it seems unlikely that *M. leprae* could penetrate normal healthy skin. Thus, only individuals with an open wound or with dermatitis would be susceptible.

The possible role of the nose and upper respiratory tract in the transmission of leprosy has been studied extensively. Pedley[93] demonstrated that although bacilli may easily be found in the nasal discharge, they are difficult to locate on the skin surface. Davey and Rees[94] demonstrated that a high percentage of bacilli that are passed out in the nasal discharge are viable and can survive up to 7 days. A single nose blow from each of 31 patients gave a mean discharge of 1.1×10^8 bacilli with a mean morphological index (MI) of 16.9%. Studies have also shown that thymectomized mice,[95] nude mice,[96] and immunocompetent mice[97] may be infected with *M. leprae* via the respiratory route and that dissemination of the infection follows this mode of infection.[95] Job summarized experimental data in mice that demonstrate that nasal mucosa and abraded skin over the cooler parts of the body are the preferred sites of entry of *M. leprae*.[98] It is thus highly likely that most cases of leprosy are contracted through the respiratory route. One major difference from tuberculosis is that *M. leprae* gains access via the upper respiratory mucosa, primarily the nose, while *M. tuberculosis* must be inhaled into the alveoli of the lung to establish infection.

A third proposed route of infection is transmission of the leprosy bacilli by insect inoculation, as opposed to

fomites simply depositing the bacilli on the skin. Reports of acid-fast bacilli in the stomachs of insects which had bitten leprosy patients appeared as early as 1912.[60] Although the theoretical risk of transmission by insects was supported by the demonstration that mosquitoes (*Aedes aegypti*) took up *M. leprae* when biting untreated patients and were capable of transmitting the infection to mouse footpads,[99] epidemiologic studies have not shown any correlation between mosquito or other insect bites and the occurrence of leprosy. These strong epidemiologic data indicate that the theoretical possibility mentioned above is not important in the epidemiology of this disease.

Several other possible sources of infection have been suggested. Beginning in 1975, it was reported that armadillos caught in the wild in Louisiana were infected with acid-fast bacilli that ultimately proved to be *M. leprae*.[100] Numerous other surveys have confirmed that this occurs in 2–6% of armadillos caught in parts of Texas and Louisiana.[101] The significance is uncertain and the problem appears to be confined to the United States and Mexico. Originally it was felt that this was not a likely source of human infection,[102] but some investigators[103,104] have found evidence that transmission of the disease from armadillos to humans may at least occasionally occur. Leprosy has also been found in a chimpanzee from Sierra Leone[105] and a sooty mangabey monkey from Nigeria. These animals might have caught it from handlers, but its apparent transmission to a second mangabey monkey housed with the first indicates that monkey-to-monkey spread can occur.[106] Evidence that *M. leprae* may exist free in nature has also been found,[107] raising the possibility that this may be the source of infection in these various animals and perhaps occasionally in man.

Perhaps of greater importance than all of these are epidemiological data[23] that show a relatively high incidence of *M. leprae* in nasal swabs from individuals in highly endemic areas with no evidence of leprosy. There are not sufficient data yet to know whether or not these carriers transmit the organism to others, how often this occurs if it does occur, and what proportion of carriers develop clinical leprosy.[23]

7. Pathogenesis and Immunity

Although the precise route of infection by *M. leprae* is unknown, early lesions are observed in the oro- and nasopharynx and in the skin over cool regions of the body, including the forehead and malar areas of the face. Destructive lesions of the nasopharynx, larynx, and hard and soft palate are well documented[108] but, since the introduction of effective antimicrobial therapy, they are seldom seen, and the organs that are of greatest concern today are the skin and peripheral nerves.

The pathogenesis of leprosy in these tissues is dependent upon the immunological capability of the individual host to develop effective cellular immunity (CMI) to *M. leprae*. Abundant antibody is produced in the lepromatous forms of the disease but does not provide any known benefit to the patient. Cross-reactive antibodies in leprosy sera may give false-positive results in serologic tests for HIV and other pathogens, however.[109]

Among those who are susceptible, the immunopathogenesis of leprosy proceeds in two phases, mediated first by mechanisms of innate and then of specific acquired immunity. Substantial evidence now indicates that genes operating at two different levels influence resistance to *M. leprae* in man. By positional cloning, a locus associated with overall susceptibility to *M. leprae* has been identified in the PARKIN/PACRG gene.[110] This codes for a ligase in the ubiquitin proteasome pathway and may modulate innate immunity to *M. leprae* through influences on processing and presentation of *M. leprae* antigens by macrophages and dendritic cells.[111] Other studies have identified an association of leprosy susceptibility with the NRAMP gene,[112] which influences transport of iron and other divalent cations across the phagosomal membrane.[113] In Section 5.11, we referenced both positive and negative data with regard to an association with the NRAMP gene. It is not clear whether these apparently conflicting results are related to differences in methodology, study designs, study populations, or to other factors.

Several additional genes have been associated with the development of different degrees of CMI to *M. leprae*, ranging from total inability to eliminate organisms at one extreme, termed lepromatous, to the ability to develop well-formed epithelioid granulomas at the other extreme, termed tuberculoid. (The clinical and histopathologic features of this uniquely broad immunopathologic spectrum are described below, Section 8, *Patterns of Host Response*.) These genes, which appear to be expressed through T-cell-mediated influences on CMI in leprosy,[114] have been reviewed recently[42] and include genes for MHC class II molecules (chromosome 10p13),[115] transporter associated with antigen processing (TAP),[116] and tumor necrosis factor alpha (TNF-α).[117,118] Macrophages (MΦ) and dendritic cells bind *M. leprae* by means of several receptors, including C-type lectins and toll-like receptors (reviewed in reference 42), and the organism is ingested into phagosomes. *M. leprae*-infected MΦ remain remarkably functional in some respects, releasing the pro-inflammatory cytokine tumor necrosis factor-α, for example, but they also release the inhibitory molecule prostaglandin E_2 and are refractory to activation by interferon-γ.[119]

Following binding of *M. leprae* to TLR-2, MΦ develop enhanced phagocytic capability, reflected by the enormous numbers of bacilli seen in lepromatous lesions. In the appropriate genetic context, they may develop further into dendritic cells with enhanced antigen-presenting capability; such cells are observed in tuberculoid lesions.[120]

After presentation of *M. leprae* antigens to T-cells and secretion of interleukin-2 (IL-2), the immune response within lesions diverges generally along two different cytokine pathways according to the different types of leprosy. Patients unable to generate sufficient CMI produce TH-2 cytokines, while those capable of developing a granulomatous response display a TH-1 cytokine profile.[121,122] The understanding of the CMI response to *M. leprae* is incomplete, and the mechanisms underlying the selection of either pathway in individual patients remain to be elucidated (reviewed in reference 42). Nor is the TH-1/TH-2 paradigm strictly observed in leprosy; in some cases a TH-0 pattern is observed.[123] A major difficulty in interpreting these human studies is an inability to determine or control for the differing duration of illness in different patients.

Immunohistological examination of cutaneous lesions reveals a predominance of CD4+ cells over CD8+ cells in tuberculoid lesions, associated with the organization of the infiltrate into epithelioid granulomas. In contrast, in lepromatous lesions, the ratio of CD4+:CD8+ cells is ≤ 1, and both types of T-cells are randomly distributed throughout the infiltrate.

Within MΦ, reactive nitrogen products kill *M. leprae*, and MΦ capable of such killing show increased expression of inducible nitrogen oxide synthase (iNOS).[124] Reactive oxygen intermediates, capable of killing *M. tuberculosis*, do not appear to harm *M. leprae*.

M. leprae is the only bacterial pathogen of man that is capable of invasive infection of peripheral nerves, and involvement of peripheral nerves is the sine qua non of leprosy. Infection of cutaneous nerves occurs very early in the disease, since hypoesthesia or anesthesia of lesions is one of the clinically diagnostic features of early lesions. Animal models suggest that *M. leprae* initially localizes on the surface of peripheral nerves, possibly as a result of lymphatic drainage from the skin, and subsequently follows the vascular supply to gain access to the endoneurial compartment of the nerve.[125]

Within the nerve, *M. leprae* cell wall molecules bind to Schwann cells via laminin receptors, including alpha-dystroglycan,[126] and are ingested by Schwann cells. Viable *M. leprae* appear to be able to inhibit acidification of phagocytic vesicles.[127] Schwann cells in vitro do not kill *M. leprae*, and in vivo they probably offer a comfortable environment within which these bacilli are able to proliferate and survive for long periods of time.[127] Early studies also suggest that the bacilli have minimal direct effect on Schwann cell gene expression and function,[128] but infected Schwann cells may be targets of immunologically mediated injury.[129]

Perineural inflammation is characteristic of leprosy, possibly reflecting the initial localization of bacilli to the surface of the nerve. The composition of the mononuclear cell infiltrates found within nerves is similar to that seen in the skin. Neuropathic pain in leprosy has only recently been appreciated and is now being studied[130] but, paradoxically, it is not nearly as frequent as might be expected from the extent of peri- and intraneural inflammation observed.

Sensitive methods for measuring functional nerve impairment have demonstrated that lepromatous patients, with focal, heavy infection of nerves, experience subtle sensory loss earlier than do tuberculoid patients,[131] although patients seeking medical attention for sensory and motor deficits are more often tuberculoid patients, in whom the severity of granulomatous inflammation apparently accelerates nerve damage more rapidly than the ineffective inflammatory response in lepromatous disease. The mechanisms of neuropathy in leprosy are poorly understood but are currently subjects of intensive investigation. Evidence to date indicates that the same immunological and inflammatory processes observed in the skin occur also in nerves, to the detriment of Schwann cells and axons.[132] Ultimately, untreated *M. leprae* infection of nerves results in demyelination and subsequent nerve conduction abnormalities in all types of the disease.[133] If untreated, this may result in permanent, profound anesthesia, paralysis, and deformity, and in autonomic neuropathy with absorption of the bones of affected hands or feet.

Neuropathy affecting the eyes deserves special note, as pointed out by Daniel et al.[134] For example, corneal nerve involvement may lead to decreased sensation, corneal abrasion, and blindness. Impaired function of the peri-orbital musculature may result in lagophthalmos.

8. Patterns of Host Response

Leprosy presents a wide range of clinical and histopathologic manifestations that puzzled and frustrated understanding of the disease until it was appreciated that this diversity was based on the ability of the host to develop a cellular immune response to *M. leprae*. Skinsnes proposed the first full formulation of the concept of an immunopathologic spectrum of leprosy in 1964,[12] and Ridley and Jopling presented a practical classification scheme based on this concept in 1966.[135] This classification enabled a reasonable

degree of global uniformity and comparison in clinical practice, and the underlying theory has become the yardstick against which new findings concerning the immunology of leprosy are measured.

Very early lesions may present histologically as relatively non-specific perineural infiltrates in which rare acid-fast bacilli can be demonstrated, but without sufficient infiltrates to classify them these are called "indeterminate" (Figure 1). Care should be taken to use this term only when the biopsy shows diagnostic evidence of leprosy (nerve involvement and acid-fast bacilli), since a diagnosis of leprosy often has significant impact on the patient's mental and physical health, social status, and employment and also impacts the patient's family.

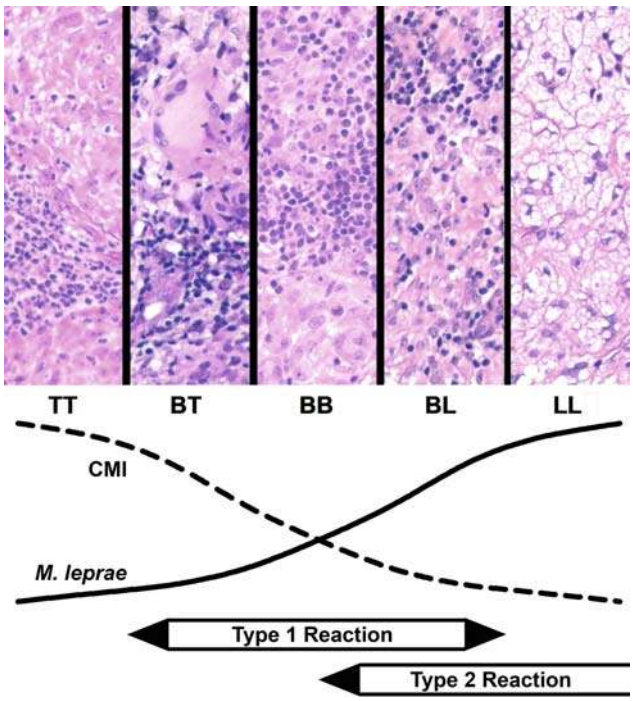

Figure 1. The immunopathologic spectrum of leprosy. Representative sections of human skin biopsy specimens illustrate the full spectrum of inflammation seen in leprosy, from the well-formed granulomatous inflammation of polar tuberculoid (TT) lesions to the completely disorganized sheets of foamy macrophages observed in polar lepromatous (LL) disease. Most patients are classified in the broad borderline region, which is further divided into borderline tuberculoid (BT), mid-borderline (BB), and borderline lepromatous (BL). As indicated in the diagram, the number of bacilli present in lesions (*solid line*) varies from rare in TT lesions to abundant in LL ones. This is inversely related to the patient's degree of cell-mediated immunity (CMI) to *M. leprae*. The *open arrows* indicate the portions of the spectrum in which patients are at risk for type 1 ("reversal") or type 2 ("*erythema nodosum leprosum*") leprosy reactions.

Among patients with established lesions,the five-part Ridley–Jopling classification identifies, at one extreme, patients with a high degree of cell-mediated immunity and delayed hypersensitivity, presenting with a single (usually), well-demarcated lesion with central hypopigmentation and hypoesthesia. Biopsy of such a lesion reveals well-developed granulomatous inflammation and rare acid-fast bacilli demonstrable in the tissues; this is termed polar tuberculoid (TT) leprosy (Figure 1). Unlike tuberculosis, caseous necrosis is rare in TT leprosy granulomas. At the other extreme, in patients who have no apparent resistance to *M. leprae*, biopsy of a raised or nodular skin lesion reveals sheets of foamy macrophages in the dermis, containing very large numbers of bacilli and micro-colonies called "globi". This non-resistant, highly infected form of the disease is termed polar lepromatous leprosy (LL). The majority of patients, however, fall into a broad "borderline" category between these two polar forms; this is sub-divided into borderline lepromatous (BL) leprosy, mid-borderline (BB) leprosy, and borderline tuberculoid (BT) leprosy, each with a correspondingly graduated bacterial load and organization of the inflammatory infiltrate (Figure 1). In the World Health Organization's simplified clinical classification scheme, TT and BT types are generally identified as "paucibacillary" (PB), and LL, BL, and BB types as "multibacillary" (MB), though there is not one-to-one correlation between the two classifications.

Overall, the majority of patients are classified in the LL, BL, or BT categories, but the distribution of patients within the entire spectrum varies according to racial background (e.g., TT and BT types are more common in African populations, and LL and BL types are more common in Caucasian populations). Patients in the two polar groups (LL and TT) are relatively stable in their immunopathologic response to *M. leprae*, but considerable shifts in immunological and clinical status can be observed in patients in the borderline portion of the spectrum. Current understanding of the genetic and immunologic basis for this broad range of human immune response to *M. leprae* has been discussed above (Immunity and Pathogenesis).

"Reactions" are acute inflammatory complications often presenting as medical emergencies during the course of treated or untreated HD. Two major clinical types of leprosy reactions occur; together they may affect 30–50% of all leprosy patients.[136,137,138] Because *M. leprae* infects peripheral nerves, the inflammation associated with reactions is often a medical emergency, as severe nerve injury may develop rapidly, with subsequent loss of sensation, paralysis, and deformity.

The cause(s), mechanisms, and treatment of these reactions remain highly problematic, both for clinicians and basic

scientists.[42] The different types of reactions appear to have different underlying immunologic mechanisms, but these are poorly understood, in spite of a substantial body of detailed descriptive information, and the factors that initiate them are unknown.

Type 1 reactions occur in patients in the immunologically labile, borderline portion of the spectrum (i.e., BL, BB, and BT). They are also known as "reversal" reactions, because clinical and histopathologic observations suggest that the cell-mediated immunity (CMI) in the lesions had increased ("upgrading") or decreased ("downgrading").[139] The increase in cell-mediated immunity against *M. leprae* is the underlying mechanism for the type 1 reaction and is most often seen after institution of effective therapy against *M. leprae*. There are other situations in which such an increase in cell-mediated immunity to *M. leprae* may occur, however.

Those experienced in caring for patients with tuberculosis are familiar with the clinical situation of radiologic progression of pulmonary tuberculosis with mild clinical symptoms in a patient receiving systemic corticosteroid therapy. When the corticosteroid therapy is stopped or the dose of corticosteroid markedly reduced, the patient may develop severe clinical symptoms due to an increase in CMI. The same may occur in leprosy, either in a patient already receiving corticosteroids when leprosy is diagnosed or in a patient with leprosy receiving corticosteroids when the dose is reduced.

Normal pregnancy is associated with a progressive suppression of cell-mediated immunity.[140] The increase in cell-mediated immunity in the postpartum state is almost certainly responsible for the postpartum type 1 reactions reported in the review by Lockwood and Sinha[141] and diagnosed in a number of patients by one of us (RIF).

The recently recognized clinical entity called immune reconstitution inflammatory syndrome (IRIS) has been reported in a number of patients with tuberculosis where the clinical manifestations of tuberculosis became more severe when the patient's CD4+ T-cell count and cell-mediated immunity increased after institution of highly active antiretroviral therapy (HAART). Although early studies did not show a significant effect of HIV on the epidemiology or clinical manifestations of leprosy, subsequently IRIS has been recognized in patients who have both AIDS and leprosy in endemic countries[77,78,109] and more recently in the United States.[142] Trindade and colleagues recently reported two patients with leprosy and HIV infection who developed type 1 reactions prior to the administration of HAART.[143] Ustianowski and coworkers reviewed the current knowledge of the interactions between HIV and leprosy in another recent paper.[144] The clinical findings and immunologic changes in leprosy-associated IRIS are identical to type 1 reactions seen in patients without HIV. The difference is that the type 1 reaction in IRIS follows an increase in CD4+ T-cells in response to HAART given prior to or concomitant with the development of the type 1 reaction.

Finally, Scollard et al. reported two patients with leprosy that became clinically apparent after treatment with infliximab, a human monoclonal antibody that binds to tumor necrosis factor-α.[145] Both patients developed type 1 reactions after discontinuation of infliximab, presumably due to restoration of cell-mediated immunity. Infliximab and other tumor necrosis factor-α inhibitors interfere with the cell-mediated immune response to mycobacteria, and treatment with these agents may precipitate clinical leprosy or tuberculosis in patients who have latent infection with *M. leprae* or *M. tuberculosis*, respectively.

These reactions often develop gradually and their natural course may last for many weeks or months. They may develop before or during the course of treatment, presenting as induration and erythema of pre-existing lesions (although new lesions may also appear), frequently with prominent acral edema, and often with progressive neuritis. They may also occur after treatment has been completed, presumably because *M. leprae* antigens remain in the body for a prolonged period even after successful treatment. Post-treatment type 1 reactions have been noted most often in patients treated with the 6-month PB regimen. It is likely to be seen more often in patients treated with the MB regimen in the future if treatment is given for 12 months rather than 24 months. In severe reactions the lesions may ulcerate. Cellular immunity to *M. leprae* is spontaneously enhanced in "upgrading" reactions, with increased levels of TH-1 cytokines in cutaneous lesions[123,146] (reviewed in reference 42). Corticosteroid treatment generally controls the inflammation in type 1 reactions, but management is empirical because no laboratory tests are available to determine when the underlying immunologic activity has ceased. Occasional patients may require very high doses of corticosteroids and rarely other drugs are necessary.[147]

Type 2 reactions, also known as *erythema nodosum leprosum* (ENL), occur in LL and BL patients who have poor cellular immunity to *M. leprae*, abundant bacilli (i.e., antigen) in skin and nerve lesions, and high levels of circulating immunoglobulins.

These patients experience an abrupt onset of crops of very tender, erythematous nodules that may develop on the face, extremities, or trunk, without predilection for pre-existing lesions. Systemically, these patients often also experience fever, malaise, and painful neuritis. Iridocyclitis and episcleritis, orchitis, arthritis, and myositis may also accompany this reaction. In severe type 2 reactions some of the

cutaneous lesions may ulcerate. The usual course of an untreated episode of a type 2 reaction is 1–2 weeks, but many patients experience multiple recurrences over several months.

The acute lesions of a type 2 reaction are characterized by a neutrophilic infiltrate superimposed upon a chronic lepromatous pattern, observations that have long dominated thinking about this reaction. Although widely regarded as an immune-complex phenomenon,[148] the evidence is not entirely convincing and some findings implicate cellular immunity in type 2 reactions,[123] reviewed in reference 42. Interestingly, attempted therapy of lepromatous leprosy by intra-lesional injection of IFN-γ elicited type 2 reactions in some patients.[149]

For type 2 reactions, thalidomide is the most efficacious drug.[150] (For decades, the type 2 reaction was the primary indication for the use of thalidomide, and the drug might well have been forgotten entirely had it not been so valuable for the treatment of this complication of leprosy.) The use of this drug is very strictly regulated in the United States because of its teratogenicity, and thus it is never the first line of treatment in this country, in spite of its efficacy. Therefore, corticosteroids are the most widely used agents for the treatment of these reactions in the United States.[151,152] In some countries, however, thalidomide is the agent of choice. The anti-inflammatory properties of clofazimine may also be useful in treating type 2 reactions. Antimicrobial therapy should be maintained throughout treatment of both types of reactions.

The Lucio phenomenon is an acute, severe, necrotizing vasculopathy occurring primarily in patients of Mexican ancestry.[153] Fortunately this complication is rare, because it is associated with high morbidity and mortality. These reactions have been associated with the presence of high levels of cryoglobulins, and *M. leprae* antigens have been associated with some of these,[154,155] but the role they might play in these reactions is unclear. Characteristically, endothelial cells are unusually heavily infected and may be seen in various stages of degeneration. Lucio reactions may be accompanied by a profound anemia, and severe cases may require intensive inpatient treatment, with debridement and wound care comparable to the management of severe burns.

9. Control and Prevention

9.1. General Concepts

Leprosy control today is based mainly on case detection and treatment. The introduction of rifampin, discovered in 1968[156] and first used for the treatment of leprosy in 1970,[157] revolutionized treatment. Rifampin is the most potent anti-*M. leprae* drug in clinical usage. It kills 99.9+% of all viable *M. leprae* within a few days. Since treated cases are thereby apparently rapidly rendered noninfectious, isolation is not required nor is hospitalization necessary for administration of antimicrobial therapy. The success of this approach, of course, depends on having an effective leprosy control program that can be either vertical or horizontal. As leprosy has become less common, horizontal programs that are integrated into the primary health care system have become more common. Guidelines for all aspects of control programs are contained in a number of the WHO publications,[14,158,159] but obviously all such guidelines must be adapted to the individual country situation. Special challenges include non-specific presentation of the disease, lack of familiarity of health care workers with the disease, stigma that makes patients and their families reluctant to report for diagnosis, and geographic barriers, all of which impede early case detection. While there is effective treatment, a major challenge is ensuring compliance with multiple drugs over a prolonged period of time. Although those working in leprosy may view today's regimens as short in comparison with previous regimens, patients do not view them as short.

Case detection has been based mainly on the examination of household contacts and the awareness of health care providers of the early symptoms and signs of leprosy. In recent years, however, it has become increasingly common that no household case or other known source case is detected. General population surveys and screening of school children or other special population groups are generally insufficiently productive in terms of detection of new cases to justify their cost. Exceptions may include areas with a high prevalence rate, particularly where the population has relatively poor access to medical care and/or the control program is just being developed, and patients previously treated with dapsone monotherapy, in whom the relapse rate is known to be high. Programmatic success is measured by detection of disease at a relatively early stage (indicating an effective program of case detection), a low disability rate in new cases (another indication of effective and early case detection), the percentage of patients who have completed treatment (indicating an effective treatment program), and a low number of cases in children (indicating limited ongoing transmission of disease). In the United States, with abundant resources and a low number of cases, the goals should clearly be curative treatment of every patient and prevention of any disability not already present at the time of diagnosis.

9.2. Antimicrobial Chemotherapy of Leprosy

Dapsone, first used successfully in 1941,[160] was the mainstay of treatment for leprosy for almost 40 years.

Although clofazimine was introduced for leprosy treatment in 1961[161] and rifampin in 1972,[162] and multidrug therapy was proven to be effective in a study in 1972,[163] dapsone monotherapy was the standard regimen from the time of its introduction until the 1980s. This is both remarkable and unfortunate. Streptomycin, the first effective antituberculosis chemotherapeutic agent, was discovered by Waksman's group in 1943[164] and first used to treat tuberculosis in 1948.[165] It soon became apparent that monotherapy of tuberculosis leads to resistance to the antimicrobial agent and that multidrug therapy is essential.[166] This has been the paradigm for treatment of tuberculosis ever since. It took nearly four decades for this concept to be applied to leprosy. Part of the reason was the inability to culture *M. leprae* and to study drug resistance. Dapsone resistance was first demonstrated in the mouse footpad in 1964.[167]

Multidrug therapy is now applied universally in leprosy control. By 1981, primary and secondary dapsone resistance had been demonstrated, with resistance rates as high as 19% in some groups of multibacillary patients with relapse.[168] A WHO Expert Committee recommended in 1981 that all patients be treated with multidrug therapy.[168] WHO developed a field classification, categorizing patients as either paucibacillary (PB) or multibacillary (MB). Though some changes have been made in the criteria for these two classes, the basic classification remains in effect, as do the treatment regimens recommended by the Expert Committee. The PB regimen consists of rifampin 600 mg, given once each month under direct supervision for 6 months, and dapsone 100 mg daily, taken by the patient without supervision for 6 months. The regimen for MB disease includes the same treatment as the PB regimen with two changes that increase the potency of therapy. First, patients also receive clofazimine, given in a dose of 300 mg monthly at the same time as the supervised rifampin dose and 50 mg taken daily with the dapsone without supervision. Second, the duration of treatment is extended to 24 months. Although the regimen that was developed in 1981 and has been only slightly modified subsequently has been administered to millions of patients, there has never been a randomized controlled trial of its efficacy. Nevertheless, its efficacy has been demonstrated by relapse rates in the range of 1% for either regimen with prolonged follow-up. Assessing the true relapse rate is difficult, as some of the PB relapses almost certainly reflect immunologic phenomena (reactions) occurring after the relatively brief course of treatment. In addition, there is no diagnostic test to differentiate relapse from re-infection. Thus, the true relapse rate is probably well below 1% with 15–20 years of follow-up. There are now data to indicate one major exception to the preceding statements regarding the efficacy of the WHO regimens. Studies strongly suggest that MB patients with very high bacillary loads (BI of $\geq$4+) have a much higher relapse rate.[169,170] Given the increased relapse rate in patients with a high bacillary load, the very slow growth of *M. leprae*, and the difficulty of detecting relapse at an early stage, it is possible and perhaps likely that relapse rates will be higher with longer periods of follow-up.

The standard approach to therapy of patients who relapse after completion of the MB regimen has been retreatment with the same regimen, as drug resistance does not seem to be a major factor in these relapses. The authors prefer increasing the potency of the regimen in the initial treatment of these high-risk patients, either by giving rifampin on a daily rather than monthly basis or by extending the duration of treatment beyond 24 months, or both, and to similarly increase the potency in patients who are retreated for relapse. There are no data, however, to tell the clinician that one or another of these three options is the best choice.

WHO has made two relatively recent changes to the standard multidrug regimen. The first relates to the MB regimen. With regard to treatment of MB disease, analysis of patients who dropped out of treatment without completing the full 24 months revealed that those who had completed at least 12 months of treatment had a much lower relapse rate than those who had completed less than 12 months of treatment. WHO stated that "it is possible that the duration of the current MDT regimen for MB leprosy could be shortened further to 12 months"[171] and now recommends 12 months of treatment with the MB regimen as the standard.[172] In view of the success of the 24-month regimen and the limited experience with the 12-month regimen, the authors recommend the 24-month regimen whenever resources permit this. This clearly applies to the United States.

The second WHO change relates to patients presenting with a single skin lesion. Because some clinical data suggest that such patients have a high rate of spontaneous cure and a low rate of relapse, WHO now recommends treatment of these patients with a regimen called ROM, which stands for rifampin, ofloxacin, and minocycline.[173] The treatment consists of single doses of rifampin 600 mg, ofloxacin 300 mg, and minocycline 100 mg, given together. Again, there have been no randomized controlled studies of this regimen. Limited data suggest that it is effective,[173,174] but there have been no large studies to compare this to other regimens and the analysis of the data has been questioned.[175] In the United States, its use should be restricted to those very few cases where compliance, drug intolerance, travel, or some other factors make it the preferred regimen.

While dapsone, rifampin, and clofazimine have been the standard drugs for more than two decades, the ROM regimen above reflects the interest in, desire for, and availability of other agents. Aside from the use of ofloxacin in the ROM

regimen, ofloxacin and other fluoroquinolones have been studied in mice[176] and humans.[177] There are also limited data concerning the effect of minocycline on *M. leprae* in humans.[178] Clarithromycin is also active against *M. leprae* and has been studied to a limited extent in humans.[179] This and other potential new drugs have been studied in animals.[180] All of these drugs are more expensive than the older agents. The cost factor could be overcome if the duration of treatment could be dramatically shortened, as with the ROM protocol. This would also have the advantage of reducing problems with compliance and reducing program costs incurred in maintaining patients on the registry and on treatment for a long period of time. Another problem, however, is that the falling incidence and prevalence of leprosy make it unlikely that there will be sufficient numbers of patients treated with these agents to determine their relative efficacy in comparison with the standard regimens.

9.3. Follow-Up after Antimicrobial Therapy

Because of the high cure rate with WHO MDT, WHO does not recommend routine follow-up of patients who have completed therapy. Rather, emphasis is put on education of the patient regarding symptoms and signs of relapse or reaction.[158] In countries with sufficient resources, programs may chose to see patients periodically following completion of treatment, both to assess the patient for relapse or reaction and to reinforce patient education.

9.4. Follow-Up of Contacts

WHO recommends[158] an evaluation of household contacts only at the time of diagnosis of the index case. Thereafter, contacts are advised to return only if signs or symptoms of the disease occur. Nonetheless, many control programs and the United States' recommendations are for annual follow-up examinations of contacts for 5 years. Early detection among contacts or the general population obviously depends on having physicians and other health practitioners who are trained to recognize the early symptoms and signs of the disease. As a result of efforts to eliminate leprosy as a public health problem by the year 2000, there has been significant improvement in this regard in most leprosy-endemic countries in recent years. Nonetheless, the effort must continue even after that goal is reached if we are to avoid a future resurgence of leprosy. The clinical examination to evaluate contacts for symptoms and signs of leprosy is equally important as it provides an opportunity to instruct the contact regarding these. Because of the variable "incubation period", patients may develop leprosy after they have completed their evaluation period or between periodic evaluations. Patients who have been properly educated will know when and how to get assistance if they are concerned, either after they have been released from the contact evaluation program or in between yearly examinations.

In the United States, the goal should be early detection and appropriate treatment of all patients. Because of the limited extent of the problem in this country, however, only household contacts or other very close contacts need to be examined on a regular basis. In selected circumstances, it may be beneficial to broaden the circle of contacts that is examined. For example, in Hawai'i, detection of a single case in an immigrant from the Republic of the Marshall Islands led to detection of a number of other cases. Subsequent active voluntary screening of many Marshall Islanders in Hawai'i led to detection of a number of additional cases.[19] If such community screening is done, it must be done with great sensitivity and with the assistance of leaders of the community undergoing screening. If these factors are ignored, the screening process is likely to be rejected by the community and members of that community may be subject to great stigma. It is doubtful that we can eliminate the disease in the United States, since most new cases occur among immigrants or aliens, but the problem is readily controllable.

Health education of patients and their families cannot receive too much emphasis, either in the United States or elsewhere. Patients will require antimicrobial treatment for 6 months to 2 years. Patients with disability, reactions, or other complications may require prolonged or lifelong care. As noted above, education is essential to ensure the cooperation of patients and their families and close contacts and to minimize stigma.

9.5. Chemotherapeutic Approaches to Prophylaxis

Chemoprophylaxis as a leprosy control measure has been attempted in a number of studies over the years since sulfone drugs were first found to be effective for the treatment of leprosy in the 1940s. Investigators reported a 40–80% success rate using dapsone.[181] Unfortunately, most had insufficient follow-up to determine whether the disease was actually prevented or only delayed in those contacts destined to develop MB disease. The best trial in this regard was carried out on the islands of Pohnpei and Pingelap in what is now Pohnpei State in the Federated States of Micronesia, which at the time of the study had a case detection rate of 7 per 1,000.[182] A relatively successful attempt was made to treat all of the population with 15 injections of acedapsone over a 3-year period. This drug is the diacetyl derivative of dapsone and, given in a dose of 225 mg every 11 weeks, maintains a low, relatively stable level of dapsone in the blood throughout the interval. As expected, the incidence of

new cases fell to zero during the trial, but cases began appearing again shortly after the trial was discontinued and continued to appear for some time. Even if acedapsone prophylaxis had been successful, the prolonged period of time it had to be given would have markedly limited its usefulness under field conditions.

A trial of a single large dose of rifampin (25 mg/kg in adults) to prevent leprosy[183] demonstrated some effectiveness but the number of patients was too small to clearly define the benefits from this approach. More recently, WHO tried two other approaches in Pacific Island populations with a high incidence and prevalence of disease. In one, they attempted to give a single dose of ROM to every citizen. In the second, they treated all known contacts of cases with the PB regimen. There are presently no data to evaluate the success of either of these approaches.[184,185] Thus, WHO at this time does not recommend any form of chemoprophylaxis to prevent leprosy.[158] In the United States, the question of prophylaxis arises occasionally, most often when a parent of a young child develops MB disease and the treating physician considers preventive treatment for the child. In most instances, as the degree of contagiousness decreases rapidly once the parent is started on treatment, it is sufficient to treat the patient and screen the child periodically. Were one to institute preventive treatment, one would have to either use the PB regimen or the ROM regimen, starting only after the parent has had sufficient treatment to permanently interrupt transmission to the child. There are no data to guide the physician regarding the duration of such preventive therapy.

9.6. Immunization

Over the years, there has been a great deal of interest in immunization to prevent leprosy. Although no specific antileprosy vaccine is yet available, BCG offers about 50–80% protection against leprosy[186,187,188] and is more effective for leprosy than it is for tuberculosis. Trials using vaccines containing two cultivable mycobacteria, *Mycobacterium w* and the ICRC bacillus, as well as heat-killed *M. leprae*, with or without simultaneous administration of BCG, showed that each of these vaccines may have some effect in preventing leprosy[188,189,190] but, given the apparent effectiveness of the current approach emphasizing case detection and curative antimicrobial therapy, it seems unlikely that they will play a significant role in global leprosy control. In addition to preventing leprosy, there is evidence that these vaccines may also have an immunotherapeutic effect on this disease. Probably related to this immunotherapeutic property, a number of studies in India have suggested that these mycobacterial vaccines might shorten the duration of MDT necessary for cure. Again, given the effectiveness of current treatment regimens and the diminishing number of patients available to participate in clinical trials, it seems unlikely that this will play a significant role in the years ahead. Nevertheless, interest in vaccine development continues. Investigators are currently using molecular approaches and attempting to develop a multipurpose vaccine that could provide protection against several diseases including leprosy.[81]

10. Unresolved Problems

Although there was failure on a global level to reach the WHO goal of elimination of leprosy as a public health problem (prevalence less than 1 per 10,000 population) by the year 2000, great progress has been made in reducing the prevalence and incidence of leprosy. The tools to continue to reduce and contain this disease are clearly at hand. The crucial factors in the years to come in terms of containment are likely to be continued action on the part of governments and non-governmental organizations to maintain leprosy control programs in the face of competition for funds from other public health problems, including infectious diseases such as the acquired immunodeficiency syndrome (AIDS), tuberculosis, malaria, and influenza, both human and avian. Specialized facilities and services have been or are being integrated into general medical services. This integration and the accompanying decrease in the number of clinicians with experience with and interest in leprosy lead to both underdiagnosis and overdiagnosis and difficulty in diagnosing new cases at an early stage. There are concomitant problems with management of acute and chronic complications of leprosy. In addition, although WHO does not include them in the number of cases of leprosy, there are many patients with severe leprosy-related disabilities who will continue to need various services, including medical care, rehabilitation, job training, and social and mental support, from control programs.

In spite of the tremendous progress that has been made in leprosy control, made possible in part by a well-funded, globally adopted WHO program, the failure to reach elimination goals in all countries and in parts of other countries reflects the pitfalls in relying solely on antimicrobial therapy for elimination.[191,192] While there have been major advances in understanding the immunologic aspects of leprosy, these changes have not yet led to the development of an effective vaccine. If such a vaccine should become available, this will require challenging decisions, such as what is an acceptable dollar cost for the vaccine, what are the costs of implementation of a vaccination program, and which populations and individuals should receive the

vaccine? A possible strategy is to develop a multivalent vaccine that would be effective for several diseases affecting populations also affected by leprosy, such as tuberculosis and malaria. This approach is in the early experimental stages of development.

While remarkable technical advances enable us to describe many immunological aspects of leprosy and its broad immunopathological spectrum at the molecular level, we still cannot explain the mechanisms that determine whether or not an individual is susceptible to developing clinical leprosy and, if susceptible, what degree of susceptibility is present. In addition, understanding of these basic mechanisms will be important in assisting clinicians in managing immunological reactions and in managing neuritis.

Treatment of leprosy immunologic reactions continues to be a challenging and important aspect of overall patient care, since reactive episodes may result in worsening of existing disability or development of new disabilities. Corticosteroids and thalidomide are, for practical purposes, the only available therapy. While both are reasonably effective for the proper indication, toxicity is a major problem with corticosteroids. Toxicity can also be a major problem with thalidomide, and the potential for teratogenicity limits the availability of this drug. It would clearly be a major breakthrough to have pharmacologic agents that are safer and at least as effective. In addition, diagnostic tests for leprosy reactions will be valuable in determining when to institute therapy and in guiding the clinician with regard to duration of therapy or dose of the agent(s) used.

The mechanisms of nerve injury in leprosy are still poorly understood, hampering more effective prevention and treatment. Nerve biopsy of seriously affected nerves is usually impossible because of the ensuing permanent loss of nerve function. Thus, most current knowledge of the processes involved has been derived indirectly, primarily from studies of Schwann cells in vitro. Although the armadillo appears to offer a good experimental model, at least in terms of the patient with lepromatous leprosy, exploitation of this model has been severely hampered by the lack of reagents for immunological studies of this animal. Successful conclusion of research to sequence the armadillo genome should offer new possibilities for determining the mechanisms involved in the pathogenesis of neuritis in leprosy.[193] Successful prevention or reversal of the peripheral neuropathy of leprosy would dramatically reduce the medical, psychological, social, and economic impacts of infection by *M. leprae*.

Better understanding of the biology of *M. leprae* and of the response it elicits in humans is required for the development of a vaccine. Although *M. leprae* still cannot be cultivated, the availability of the complete genome and related molecular discoveries should in time provide answers to a variety of questions. Comparison of the genome of *M. leprae* with other pathogenic mycobacteria, including *M. tuberculosis*, may provide insight into why *M. leprae* cannot be cultivated and how it is so successful in maintaining existence as a non-toxic intracellular parasite in some patients. Genomic information has already led to the identification of mutations associated with drug resistance and of genes controlling protein production that may be important immunologically. Identification of genomic patterns in strains of *M. leprae* may yield information that leads to a better understanding of its epidemiology and transmission.[6]

The standard diagnostic tests for *M. leprae* have been slit skin smears and punch biopsy of the skin. The former has low sensitivity and is difficult to maintain quality control. The latter is invasive and requires physicians to process and interpret the specimen. These resources are not available in all localities and thus skin biopsy will not be practical for broad use. The WHO field classification has proven to be useful but is likely to decrease in utility as leprosy becomes less common. It is also meant for less developed countries and does not have a major role in the United States. It seems likely that serologic diagnosis will not play a major role in leprosy control. While PCR has promise, the test will need to be modified to have better sensitivity and specificity, to be useful under field conditions, and to be less expensive.[194,195] Thus, improved methods for diagnosis and follow-up of patients are important and may become even more important as control programs are more and more integrated into primary health care. In addition, there are no reliable laboratory tests to diagnose leprosy immunologic reactions or to assess the severity of such reactions. Hopefully identification of the mechanisms underlying such reactions will lead to development of such diagnostic tests.

PCR has demonstrated the presence of *M. leprae* in the nose of individuals without clinical signs or symptoms of leprosy. Questions that must be answered include the following: (1) Is there a way to determine which of these individuals will develop clinical leprosy? (2) Are these individuals contagious during the period of nasal carriage? and (3) What is the typical duration of nasal carriage? Related to these questions is the question of the role of non-human sources of leprosy. Finally, PCR or some other test must be developed to aid in differentiating relapse from re-infection.

As discussed in Section 9.2, it is possible that 12 months of therapy is sufficient for most patients, and it is clear that some patients (PB and single lesion) can be treated with shorter courses of therapy. An important question is whether it is possible to select those MB patients who can be successfully treated with less than 24 or 12 months of therapy, just as it is clear that some patients (BI $\geq$ 4) require more than 24 months of therapy. Likewise, it is unclear whether newer

drugs, either those currently available or those yet to become available, will play a significant role in leprosy control. If the number of patients continues to fall, it will become increasingly difficult to conduct scientifically valid trials of new agents.

CHAPTER 21

Leptospirosis

Paul N. Levett and Charles N. Edwards

1. Introduction

Leptospirosis in humans occurs globally[141] as an acute infection ranging in severity from unnoticed and subclinical to fatal. It is a zoonosis (strictly, an anthropozoonosis) acquired by humans from an animal source. The causal bacterium is a pathogenic spirochete of the genus *Leptospira*, of which there are several species and more than 250 serological varieties (serovars), each of which has some diagnostic, prognostic, or epidemiological significance.[50,70]

The ultimate reservoir of all leptospirosis is a non-human carrier animal that excretes the causal bacteria (leptospires) in its urine. In animals, the leptospires infect primarily young animals, which may become renal carriers and urinary excreters if they survive an acute initial infection. Human-to-human transmission has been recorded extremely rarely, congenital infection has been infrequently reported, and laboratory-acquired infections have been documented rather more frequently.

There are a large number of leptospires identified by serology or by genetic relationships. In general, there is a correlation between animal reservoir, serological type (serovar), and potential severity of the illness. The disease has many local and folk names, frequently originating from historical or clinical features or associated occupations, such as "pretibial fever," "swineherds' disease," "cane-cutters disease," "mud fever", "pea-pickers' disease" or "swamp fever".

As it is a zoonosis, leptospirosis is most significant for those whose work or leisure brings them into contact with infected animals or their urine. It is highly related to occupation in societies where animal contact is rare except through work. In tropical areas especially, it is impossible to avoid direct or indirect contact with feral carrier rodents or with livestock. In other areas, only those in selected occupations are exposed to significant risks. The public health importance of leptospirosis lies in its occupational, seasonal, and sex- and age-related incidence; the acute and sometimes prolonged incapacity for work; loss of human and livestock productivity; costs for medical care, workers' compensation, or similar insurance payments; and preventive measures. It can be epidemic, sporadic, or endemic.

2. Historical Background

The early history of leptospirosis is vague, because it was not possible to differentiate the different forms of "malignant jaundice," which included hepatitis, yellow fever, leptospirosis, and malaria, until scientific clinical and pathological knowledge had progressed into the 1880s. The history of leptospirosis was reviewed by Faine[50] and by Everard.[48] The clinical entity was described by both Mathieu and Weil in 1886, but Weil's description became the classical reference. The syndrome of fever, hemorrhage, jaundice, and enlarged liver and spleen, with renal failure, became known as "Weil's disease." Its etiology was unknown until the discovery of pathogenic leptospires, first seen in stained tissue sections of liver from a "yellow fever" patient, and later cultivated independently from Weil's disease patients among coal miners in Japan in 1914 and German troops in trenches during World War I in 1915. It was named *Spirochaeta icterohaemorrhagiae* by the Japanese; *Spirochaeta icterogenes* by the Germans; and later *Leptospira icterohaemorrhagiae* by Noguchi. Both the Japanese and German workers and their associates quickly published much of the basic knowledge of the microorganisms, as well as the pathogenesis, pathology, clinical features and diagnosis, and rodent source of leptospirosis.

Paul N. Levett • Saskatchewan Disease Control Laboratory, Saskatchewan Health, Regina, Saskatchewan, Canada S4S 5W6. **Charles N. Edwards** • Queen Elizabeth Hospital, St. Michael BB11155, Barbados, West Indies.

Less severe illnesses were soon recognized as forms of leptospirosis. Dogs were identified as both reservoirs and susceptible animals. Once the wider range of clinical manifestations was recognized, other serovars were isolated from patients and carrier rodents and were identified, so that by the mid-twentieth century, 45 serovars significant for human leptospirosis and their reservoirs had been identified.

A major discovery was that livestock (pigs, cattle) could be carriers and could excrete large numbers of leptospires in urine. Both primary (rodent–rodent) and secondary (rodent–livestock–rodent) cycles were identified. The range of known serovars continued to expand, mainly following research in tropical countries. Although leptospires could be isolated by culturing blood or urine from patients, evidence of leptospirosis was obtained mainly by serological tests on patients' sera. Most culture media required rabbit serum. The use of bovine albumin and oleic acid or polysorbate-linked fatty acids (Tween) to replace rabbit serum was an important advance, facilitating laboratory cultivation and allowing the easier isolation of serovar Hardjo, a major cause of human leptospirosis wherever there are dairy cattle. The subtype "hardjoprajitno" was originally isolated from an Indonesian patient, and the subtype "hardjobovis" later, from cattle. Antibodies to Hebdomadis-group leptospires were already known to be prevalent in both humans and cattle. Genetic typing of leptospires, first done in the 1960s by DNA–DNA hybridization, was a major step that led much later to formal recognition of genospecies of *Leptospira*.

Vaccines for control of leptospirosis in dogs were introduced in 1939 and in pigs and cattle soon after. These vaccines would also indirectly assist in protecting humans by reducing excretion of leptospires by animals. Further developments in knowledge of microbiology of leptospires and of pathology, pathogenesis, immunity, epidemiology, and control of leptospirosis are reflected in improved laboratory and diagnostic methods during the 1980s. Recent rapid progress in the understanding of the molecular biology of leptospires has led to the identification of several significant outer membrane antigens. The genomes of several strains have now been sequenced and comparative studies are underway.

3. Methodology

The diagnosis of leptospirosis usually depends on laboratory confirmatory tests. Laboratory tests may be unavailable or delayed, because the diagnosis is not considered at an early state or because the patient is not seen until late in the illness. Failure to use appropriate laboratory tests at the proper time can lead to misdiagnosis in both suspected and unsuspected patients. Because of diagnostic deficiencies, mortality, morbidity, and incidence data based on unconfirmed diagnoses or confirmed diagnoses of a few selected patients are fallacious, almost without exception.

3.1. Sources of Data

The World Health Organization (WHO) has recommended that leptospirosis be a notifiable disease. Notification may be based on hospital admissions and diagnosis, discharge data, notification by physicians, or laboratory notification of infections diagnosed by isolation of leptospires, or on seroconversion, or both. Laboratory notification results in the recording of higher morbidity rates than practitioner notification. This is partly because patients are discharged, or recover, or die before all laboratory results are returned to practitioners, who may then see notification as useless. Follow-up of patient contacts has led to detection of cases, not because of the contagiousness of the disease, but because local outbreaks have been detected as a result of inquiries.

Death notifications and autopsy reports have been used. Accurate postmortem diagnosis is impossible where autopsies are forbidden by custom or belief. Antemortem diagnosis is required for accurate death notification without an autopsy. Mortality rates may be spuriously high if the diagnosis is made only in advanced cases who are nearly moribund when medical or hospital assistance is sought.

Expression of mortality or morbidity statistics in terms of a total population can give a false index of incidence or prevalence if the disease is not homogeneously distributed in that population, or unless a correction is made for risk of exposure. In a large predominantly urban population, an overall low morbidity rate may mask a very high rate in a selected group of that population, such as sewer workers, abattoir workers, or meat packers. Statistics should be refined and expressed in rates relevant to the size of the population at risk.[50]

Leptospirosis is not a notifiable disease in many jurisdictions, including the USA, where the disease ceased to be nationally notifiable after December 1994[24] but remains so in some states.

3.2. Surveys

Serological surveys have been used frequently in studies of leptospirosis. They can be used on unselected populations to see whether leptospirosis exists at all. In such studies it is necessary to use a battery of antigens in agglutination tests to ensure that representative serovars of all serogroups are included. Locally prevalent serovars must be included, if they are known.

Survey information can be used to show which serovars are likely to be prevalent, by analyzing results of tests on batteries of antigens, or by retesting broadly reactive sera against individual serovars. Many sera will react with more than one serovar, however, because several serovars have antigens in common, and the highest titer is not necessarily against the infecting serovar, especially following recent infections. The fact that leptospirosis may not be distributed homogeneously in the population should be borne in mind when planning surveys. The survey should be properly planned to request necessary information such as age, sex, occupation, travel, and previous known leptospirosis or similar undiagnosed illness. Adequate statistical planning beforehand is essential to ensure that an appropriate number of samples are taken in each group and that results can be analyzed by statistical techniques.

Once the presence of leptospirosis is known or detected in a survey, the data may be used to determine the population groups exposed to a risk or risks and once those are delineated, to measure the prevalence of antibodies in one or more selected subgroups. Another important function of surveys is to ascertain prevalence for evaluating control measures, both for a baseline level before their introduction and during and after implementation as part of their evaluation.

The presence of IgM antibodies may be surveyed using ELISA, allowing large numbers of sera to be tested relatively quickly. IgM antibodies usually indicate relatively recent infections. Survey information can be important for interpretation of diagnostic serology in acute cases to establish whether the patient is one of a population or subgroup in which there is a known high prevalence of antibodies.

Serological or bacteriological surveys have proved valuable in investigating outbreaks. Information may be obtained retrospectively from serum bank specimens collected from epidemic patients or from patients and their surrounding population in general concurrently with an epidemic. Apart from epidemics, surveys of serum banks have been used to ascertain overall prevalence rates in certain clinical groups, such as patients with jaundice and fever, undiagnosed aseptic meningitis, or pyrexia of unknown origin.

Prospective surveys offer a better chance of understanding the incidence of leptospirosis and the prevalence of antibodies in selected groups. These may be carried out on selected groups of hospital admissions or patients in primary healthcare clinics or practices. A suitable protocol is to carry out diagnostic tests for leptospirosis on all clinically suspected patients.[41,45,46,88] If serology is tested, a matched control series, such as nonfebrile patients, must be included.

Collection of specimens for survey purposes requires prior ethical review and the obtaining of informed consent from individual survey subjects. Where surveys are carried out as part of national or international research programs, it is essential that local customs, traditions, and religious practices of the population are respected and the surveys are carried with their cooperation.[50]

3.3. Laboratory Diagnosis

In the absence of clear characteristic clinical features, especially in mild leptospirosis, laboratory diagnosis is essential. Its importance cannot be overstated, because it is also the basis of epidemiological statistics and preventive policies and programs. Not only must the diagnosis be established as leptospirosis, but the causal leptospire should be identified, at least by serogroup, and preferably also by isolation and identification of serovar and genospecies, for prognosis, management, and prevention activities.

3.3.1. Isolation and Identification of Leptospires

3.3.1.1. Classification and Nomenclature of Leptospires. All leptospires are similar in appearance and culture. Historically, they were classified into serovars and serogroups by serology using cross-agglutination with rabbit antisera and a microscopic endpoint.[37] All pathogens were grouped in a serologically defined species known for years as "*L. interrogans*," and nonpathogens were similarly grouped as "*L. biflexa*." Now the members of the genus *Leptospira* are classified by genetic relationships into distinct species (genospecies, see Table 1). Phylogenetic analysis shows the existence of three clades with the genus, comprised of pathogens, saprophytes and an intermediate group of uncertain pathogenicity (Figure 1). Genera of *Leptonema* and *Turneriella* are recognized, comprising morphologically similar spirochetes. Many strains are not yet classified by genotype. Several strains of leptospires classified serologically by their antigens as members of a single serovar are found to belong to different genospecies; that is, more than one species may express the same serovar-specific antigens.[51,64]

3.3.1.2. Culture. Culture media containing long-chain fatty acids such as oleic acid or Tween with 1% bovine serum albumin as a detoxicant are used widely. A common formulation is the Ellinghausen–McCullough–Johnson–Harris (EMJH) medium. It is usually used in liquid form in screw-cap containers. In tubes of semisolid media containing 0.1–0.2% agar, growth occurs in one or more zones (Dingers' rings) situated from just below the surface to deep in the medium. In fluid media, growth from inocula of 1–10% of volume can be seen as a birefringent swirl in 3–20 days, depending on the individual strain. Heavier growth, always less than the turbidity seen in cultures of enteric bacteria, may be encouraged by shaking during incubation. Optimum temperature for the cultivation of laboratory strains is 28–30°C. Most strains grow poorly if at all at 37°C.

Table 1. Species and Some Serovars and Serogroups of the Genus *Leptospira*

Species	Serovar	Serogroup	Serovar	Serogroup

Leptospira genomospecies 5	Saopaulo	Semaranga		

Cultures of properly collected clinical material cultured shortly after collection are highly sensitive and capable of detecting very small numbers of leptospires after incubation for from 2 or 3 days to several weeks. Cultures should be examined at least weekly and incubated for 4 weeks to 2–3 months.

3.3.1.3. Specimens for Culture. Blood cultures taken during the first few days (up to 10 days, especially in the first week) during the fever are frequently positive. Addition of 100 μg/ml of 5-fluorouracil is useful to reduce risks of overgrowth by bacteria from contaminated specimens. Special culture media are available for isolating fastidious leptospires currently found mainly in veterinary practice.[42]

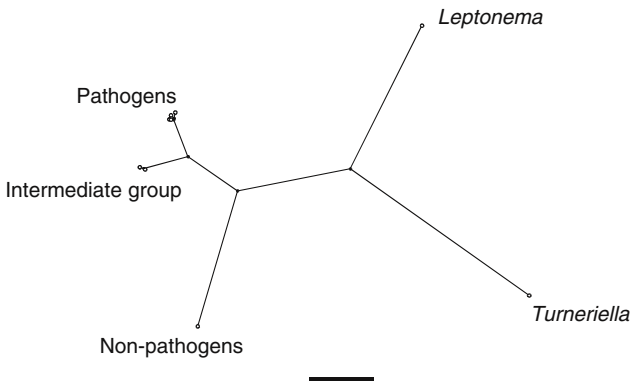

Figure 1. Phylogenetic relationships based on 16S rRNA gene sequences between the genera of the *Leptospiraceae*. The scale *bar* represents a 2% difference in sequence. See Table 1 for a list of species in the three clusters within *Leptospira*. Adapted from (72) with permission of the publisher.

Cultures may also be taken from cerebrospinal fluid (CSF), urine, and tissue samples, including autopsy specimens. Semisolid medium comprising EMJH with 0.1% agar and 100 μg/ml of 5-fluorouracil is useful for tissues.

3.3.1.4. Microscopy and Examination of Cultures. Dark-field microscopy by an experienced person is used to recognize leptospires in cultures. Leptospires appear as motile, bright, beaded, rotating, thin rods, usually with one or both ends curved, against a black background. Direct examination of clinical specimens by dark-field microscopy is both insensitive and nonspecific.[131]

3.3.1.5. Staining. Leptospires are poorly stained by conventional microscopic stains. They may be visualized by Giemsa or silver deposition methods. Silver deposition by one of several methods can be used for tissue sections, but flawless technique is required to obtain clean, interpretable results. Immunohistochemical staining has both greater sensitivity and specificity than other staining methods.[144] However, the major disadvantage of all immunostains is the need for specific antiserum. A battery of antisera may be required if the serovar is unknown or unsuspected. In extreme cases, where the infection is due to a new serovar, only convalescent patients' sera can be used as a source of the primary antibody for the test until the new organism has been isolated and immune sera prepared from it. Results of direct microscopy or immunostaining can be obtained in minutes to a few hours.

3.3.1.6. Serological Typing. If a leptospire is isolated, it must be identified by agglutination with reference antisera or serogroup- and serovar-specific monoclonal antibodies.[37,120] These identification procedures are usually performed only in reference laboratories. A list of species recognized currently, with the frequently isolated serovars and their serogroups, is provided in Table 1. A list of pathogenic serovars and their history[67] is now out of print, but is being revised.

3.3.1.7. Molecular Methods. A number of conventional PCR assays were developed for detection of leptospires, but few were subjected to clinical trials to evaluate their use in diagnosis of leptospirosis in man[18,87] or in animals.[61,135] The most widely used assays were based upon different approaches: one detected all pathogens using two quite different targets,[59] while the other used a genus-specific 16S rRNA target.[86]

Recently, real-time PCR assays have been developed, again using 16S rRNA targets.[89,116] However, recent advances in the understanding of the molecular biology of leptospires have led to the design of assays that target virulence factors expressed by pathogenic leptospires.[75,96] Real-time PCR assays are potentially more sensitive than conventional assays. One assay has been evaluated and shown to have sensitivity and specificity comparable to culture.[111]

The genospecies of *Leptospira* were defined by DNA–DNA hybridization,[16,99,102,143] but this is not a practical approach to identification of isolates. Sequence-based identification of *Leptospira* species offers an alternative, using 16S rRNA gene sequencing,[90] but within the nonpathogenic clade in particular the 16S rRNA sequences are highly conserved. Other targets may have better discriminatory power and are currently being investigated.[69,114]

Molecular methods employed for serovar identification have included digestion of chromosomal DNA by restriction endonucleases (REA), restriction fragment-length polymorphisms (RFLP), ribotyping, pulsed-field gel electrophoresis (PFGE), and a number of PCR-based approaches.[70] Currently, the most readily applicable molecular method for identification of serovars is PFGE.[62,63] This approach has been standardized using the PulseNet model.[55]

More recently, sequence-based methods such as amplified fragment-length polymorphism (AFLP) and multiple-locus variant repeat analysis (MLVA) methods have been developed for the study of leptospiral epidemiology.[79,105,112,113,130] The use of multi-locus sequence typing is being investigated.[2] The application of these tools will enhance understanding of leptospiral epidemiology at a population level.

3.3.2. Serological Tests. Antibodies in sera from patients or survey subjects can be detected and measured directly by agglutination of leptospires or by ELISA. Tests used for diagnoses of acutely ill patients need to be specific and performed rapidly if they are to aid in management and prognosis, as well as for detection of sources common to

several patients and for prevention. For epidemiological and survey purposes, there is less urgency for obtaining test results, but laboratories should be able to test large numbers of sera rapidly if necessary. Usually, knowledge of the serovar specificity of reacting antibodies is required, especially where several serovars are endemic, each with a different reservoir and pattern of transmission.

The microscopic agglutination test (MAT) is the gold standard test but requires significant expertise to maintain and interpret. IgM detection using ELISA is more widely used in diagnostic laboratories.

3.3.2.1. Agglutination Tests. The reference method for serological diagnosis of leptospirosis is the microscopic agglutination test (MAT), in which patients' sera are reacted with live antigen suspensions of leptospiral serovars. After incubation the serum/antigen mixtures are examined for agglutination by dark-field microscopy and the titers are determined. Appropriate quality control sera of known high- and low-specific reactivity are included as controls. The authenticity of strains used in antigen suspensions should be checked periodically against reference antisera. An external quality control program is organized by the International Leptospirosis Society.[26]

The range of antigens used should include serovars representative of all serogroups[125] and all locally common serovars. The highest titer is sometimes recorded against a cross-reacting serovar. Where several serovars from different serogroups are prevalent locally, there is a need to test each patient's serum against each of them or at least against a representative serovar of each serogroup. This means that in many tropical areas, or where the likely infecting serovar is unknown, a battery of up to 30 serovars may be used for each serum. There is no satisfactory single group antigen with which all patients' sera will react. The MAT is a serogroup-specific assay. Often, it becomes possible to distinguish a predominant serogroup only months after infection, as cross-reacting titers decline at different rates.[78] It is thus important if possible to examine serial convalescent specimens, in order to determine the presumptive infecting serogroup. The ability of convalescent MAT titers to predict the infecting serogroup may be as low as 40%.[71]

Interpretation of the MAT depends on the stage of illness, the serovar, and local epidemiology. Acute infection is suggested by a single elevated titre detected in association with an acute febrile illness. The magnitude of such a titre is dependent upon the background level of exposure in the population, and hence the seroprevalence. Thus a titre of $\geq$200 is used to define a probable case with a clinically compatible illness.[24] This may be appropriate for use in a population where exposure to leptospirosis is uncommon, but in most tropical countries a higher cut-off titer is necessary for defining probable cases of leptospirosis. In endemic areas a single titer of $\geq$800 in symptomatic patients is generally indicative of leptospirosis.

Paired sera are required to confirm a diagnosis with certainty. A fourfold or greater rise in titre between paired sera confirms the diagnosis, regardless of the interval between samples. The interval between first and second samples depends on the delay between onset of symptoms and presentation of the patient. If symptoms typical of leptospirosis are present then an interval of 3–5 days may be adequate to detect rising titers. However, if the patient presents earlier in the course of the disease, or if the date of onset is not known precisely, then an interval of 10–14 days between samples is more appropriate. Less often, seroconversion does not occur with such rapidity, and a longer interval between samples (or repeated sampling) is necessary. MAT serology is insensitive, particularly in early acute-phase specimens.[32]

MAT interpretation is complicated by cross-reactivity that occurs between different serogroups, especially in acute-phase samples. Titers following acute infection may be extremely high ($\geq$25,600) and may take months, or even years, to fall to low levels.[33,78,104] Rarely, seroconversion may be delayed for many weeks after recovery, and longer serological follow-up will be necessary to confirm the diagnosis.

The MAT is the most appropriate test to employ in epidemiological sero-surveys, since it can be applied to sera from any animal species, and because the range of antigens utilized can be expanded or decreased as required. Only one specimen is required for epidemiological and prevalence surveys. Serum may be frozen during transport and storage. It is usual to use a titer $\geq$100 as evidence of past exposure.[50] However, conclusions about infecting serovars cannot be drawn without isolates; at best the MAT data can give a general impression about which serogroups are present within a population.[71] Antibodies persist following clinical or subclinical infection for long periods.[11,33,78]

The MAT is a complex test to control, perform, and interpret.[125] Live cultures must be maintained of all the serovars required for use as antigens. This applies equally whether the test is performed with live or formalin-killed antigens. The labor-intensive nature of the test leads to observer error and fatigue following prolonged reading of tests. Interpretive errors may result from the use of inappropriate serovars in the panel of antigens. Direct measurement of specific IgM or IgG in MAT is not feasible. The repeated weekly subculture of large numbers of strains presents hazards for laboratory workers and laboratory-acquired infections have been reported.[4,100] Other drawbacks include the continuous risk of cross-contamination of the antigen cul-

tures, necessitating periodic verification of the identity of each serovar. MAT titers are also affected by the culture medium in which the antigens are grown.

3.3.2.2. Enzyme Immunoassay (ELISA). Detection of IgM antibodies by ELISA has been widely applied[1,121] for diagnosis of human leptospirosis. ELISA products are available commercially in several formats[74,115,140] and are widely used for screening specimens before testing by MAT. ELISA tests do not measure the same antibodies as those in agglutination tests, so there is little correspondence between the optical densities or titers in ELISA and the agglutinating titer in MAT. In pigs and cattle, blood levels of IgM reacting in ELISA have been correlated with renal excretion of leptospires.

4. Biological Characteristics of the Organism

Leptospires are tightly coiled spirochaetes, usually 0.1 μm × 6–20 μm, but occasional cultures may contain much longer cells. The helical amplitude is approximately 0.1–0.15 μm and the wavelength approximately 0.5 μm.[50] The cells have pointed ends, either or both of which are usually bent into a distinctive hook (Figure 2). Two axial filaments (periplasmic flagella), with polar insertions, are located in the periplasmic space.[118] Leptospires exhibit two distinct forms of movement, either translational or rotational. Dark-field microscopy of a wet preparation shows leptospires rotating rapidly around their long axis and translationally motile in either direction. One or both ends are usually hooked, imparting a looped appearance to the end of the leptospire when it rotates rapidly. In semisolid agar media, movement is slowed. Morphologically all leptospires are indistinguishable, but morphology of individual isolates varies with subculture in vitro and can be restored by passage in hamsters. Leptospiral lipopolysaccharide has a similar composition to that of other gram-negative bacteria.[20]

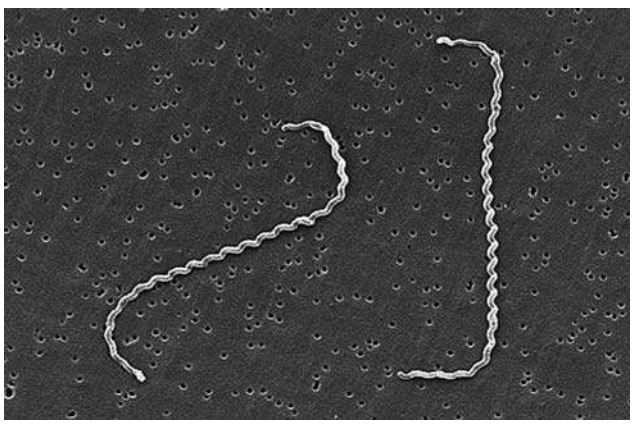

Figure 2. Scanning electron micrograph of leptospiral cells bound to a 0.2 μm filter. Magnification, approximately ×3,500. (Courtesy of Janice Carr, Public Health Image Library, Centers for Disease Control and Prevention).

All members of the genus *Leptospira* are obligate aerobes or microaerophiles with an optimum growth temperature of 28–30°C at pH from 7.2 to 7.8. They produce catalase, oxidase, and urease. Many strains produce lipase. They grow in simple media enriched with vitamins (vitamins B2 and B12 are growth factors), long-chain fatty acids and ammonium salts. Long-chain fatty acids are utilized as the sole carbon source and are metabolized by β-oxidation.[64] Phenotypic tests are not helpful for identification of leptospires, which must be identified by a combination of molecular and serological approaches.

Leptospires are easily killed by drying, by moderate heat (above 42–45°C for a few minutes), by acid conditions (below pH 7.0) or alkaline conditions (above approximately pH 7.8), and by disinfectants such as phenolics, quaternary ammonium derivatives, halogens, and aldehydes (formaldehyde, glutaraldehyde).

The leptospiral genome is comprised of two chromosomes, approximately 3500–4300 kb and 300–350 kb in length respectively. The genome of *L. interrogans* is approximately 4800 kb in size,[95,103] while that of *L. borgpetersenii* is approximately 15% smaller.[21] Leptospires contain variable numbers of rRNA genes, which are widely spaced on the larger chromosome. Numerous repetitive elements have been identified; several are insertion sequences, and are found in many serovars, but the copy number varies widely between different serovars and among isolates of the same serovar.[14] Genomic rearrangements resulting from multiple translocations have been identified.[21,95]

A wide range of antibiotics is effective against leptospires in the laboratory, although penicillin, cefotaxime, ceftriaxone, and doxycycline are widely used therapeutic agents, and doxycycline is recommended for chemoprophylaxis.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Statistics of prevalence and incidence are influenced frequently by the lack of reliability in diagnosis and by failure to recognize the selective risk to population groups. Prevalence figures derived from planned surveys are much more reliable than those based on hospital records or disease notifications. Antibody prevalence rates in tropical countries with

large feral and peridomiciliary rodent populations are much higher than in temperate climates, where leptospirosis tends to be more occupationally segregated.

Reported statistics are also influenced by technical factors such as the starting dilution for sera, the interpretation of low titers, and the techniques used for serology. These factors are often not clear from reports. When using prevalence statistics for epidemiological and control policy planning, it should be noted that the duration of persistence of antibodies after infection is variable.

Second infections with a different serovar have been reported, indicating that there is little cross-immunity between serogroups. Very rare reports of second infections with the same serovar are poorly documented.

In the United States, approximately 100 cases of leptospirosis are reported each year; however, the disease is not notifiable in many states and national data have not been collected for over 10 years. Cases occur throughout the country, but they are most common in tropical regions (Hawaii and Puerto Rico).

5.2. Epidemic Behavior and Contagiousness

Leptospirosis is not considered to be contagious, because spread from human to human is almost unknown and direct inoculation into the body via skin, mucosal, or conjunctival penetration is required for infection. Laboratory infections, a significant occupational problem, have occurred after inoculation into the eye or through the skin.[100] In natural infections an animal source of infection is required, with the rare exception of transplacental infection. Animal urine is the most important vehicle of infection for man, but direct contact with infected animals, their tissues or other body fluids are also important methods of transmission.

Significant changes in the epidemiology of leptospirosis have occurred in recent years. In developed countries the disease is much less prevalent than it was in the mid-twentieth century, for several reasons. Increasing urbanization has reduced the opportunity for exposure in the rural environment and immunization has largely controlled the disease in domestic animals. However, against this background there remain foci of infection, such as the recognition of continuing rat-associated leptospirosis in inner cities[132] and the emergence of canine infection in Eastern North America caused by serovars Grippotyphosa and Pomona,[101,136,137] presumably acquired from racoons, skunks or possums. There has been a significant rise in travel-associated leptospirosis, often associated with adventure tourism in the tropics,[25,109] and invariably associated with exposure to fresh water. By far the greatest epidemiological change globally has been the recognition of large outbreaks of leptospirosis associated with excess rainfall.[68,91,122,142] These outbreaks often occur in regions where diagnostic capacity is least well developed.

Although leptospirosis is a zoonosis, human social factors are most important in epidemiology. Occupational exposure to animals and contaminated environments is important, but avocational factors, such as housing conditions, sanitation, food storage conditions, livestock and domestic animals, and social and religious customs all affect the likelihood of exposure to leptospirosis.

5.3. Geographical Distribution

Leptospirosis is distributed worldwide,[141] wherever fresh water and carrier animals occur. There is a direct relationship with soil and geologic environment, which can affect the ability of leptospires to survive in surface waters and mud and soil through their effects on acidity and porosity.[65] Environmental changes will affect the magnitude of the risk of human leptospirosis, either positively or negatively.[98,133]

5.4. Temporal Distribution

Throughout the world, leptospirosis is related to wet periods of the year. The wet seasons, whether monsoon, floods, or spring and summer, are associated with surface conditions favoring leptospirosis in all parts of the world. In temperate climates the risks increase with fresh spring and summer growth of pastures. Risks also increase for harvest workers for many crops but not wheat or corn. Well-documented epidemics have been recorded during rice, sugarcane, and pea harvests.

5.5. Age

Although leptospiral antibodies can be found in people of all ages, the predominant incidence of acute infection is found in the 20- to 50-year age range, though in developing countries more cases may be seen in younger people. Pediatric and congenital infections have been described. The age distribution reflects the relative amount of environmental exposure to risk factors in the age groups concerned

5.6. Sex

Leptospirosis is predominantly a disease of males between the ages of 10 and 59 years. The case-fatality rate is age-dependent, rising to almost 30% in elderly adults.

5.7. Race

There is no evidence for any risk factors determined by race. Very little attention has been paid to genetic determinants of susceptibility to leptospirosis, but one recent study has shown that HLA-DQ6-positive triathletes were at greater risk of acquiring leptospirosis.[76]

5.8. Occupation

There is a strong occupational trend in all regions. Even in tropical climates, those whose jobs bring them into indirect contact with animals via rodent urine contamination in such activities as rice planting and harvesting, fish farming, forestry, mining, boating, and military exercises are at special risk. In all climates those exposed to urine contamination directly or indirectly from livestock and domestic dogs and rodents have a greater risk and increased incidence of infection. Occupational hazards involve special considerations of preventive measures to protect workers. Some countries have workers' compensation schemes which apply to persons who acquire leptospirosis at work.

5.9. Occurrence in Different Settings

Leptospirosis poses a special problem after natural disasters or in case of civil disruption. Rodent infestation may increase and with it risks to humans from leptospirosis as well as other zoonoses. Military, paramilitary, police, or civilian emergency workers may be forced into conditions such as floods and destroyed buildings that house rodents. Frequently, troops have been exposed to leptospirosis in rat-infested trench warfare or in jungle warfare or exercises. Modern leisure activities have attracted city dwellers to rural settings, sometimes in faraway lands, in search of adventures in canoeing, rafting, caving, and climbing. The risks of contracting leptospirosis on these vacations need to be emphasized, but it is important to recognize that the activities themselves put the participants at risk in temperate regions as well as tropical regions.[12,84,91,110,124]

5.10. Socioeconomic Factors

It is difficult to calculate the costs to society of the effects of leptospirosis. Some of the factors to be considered are the costs of labor to replace sick workers; the cost to the self-employed or peasant farmer or villager in money to replace his own inability to produce food for his family, and in pain and sometimes chronic illness; costs of medical attention including hospital and medical services; and costs in insurance for lost work, production, and workers' compensation. The first requirement is adequate diagnosis so that the actual impact of the disease can be assessed. However, costs of special diagnostic services and surveillance for leptospirosis are hard to justify if there is an impression that the disease is rare or absent, so that the circular logic leads to continued underdiagnosis and underreporting. Existing mild illnesses have frequently and easily been attributed to numerous other causes, including "influenza" or "viral infections", but may well be leptospirosis. Moreover, when diagnostic capacity does exist, the erroneous perception may occur that leptospirosis is more prevalent than in neighboring regions where no cases are diagnosed.[49]

An important socioeconomic consideration is the effect of leptospirosis on productivity of animals used for food or burden. Leptospirosis can cause abortions, stillbirths, failure to thrive, retarded growth, milk failure or spoilage for human consumption, and loss of productivity in meat animals among livestock. These effects can in themselves place an additional burden of malnutrition on people already threatened by the risk of illness.

6. Mechanisms and Routes of Transmission

Leptospirosis is transmitted primarily from its animal host reservoirs by urine. Excretion in urine may be intermittent or continuous and may contain very low numbers or very large numbers of leptospires; all of the former may occur at different times in a single animal. The reasons for the variable output are not known. Urine from carriers frequently contains antibodies to the homologous serovar of leptospires. The intermittent shedding, the difficulties of detecting small numbers of urinary leptospires in livestock, and the potentially enormous load of leptospires excreted into the surface water and soil environment from heavy feral rodent environmental contamination are the main sources of difficulties in control in different situations.

Pathogenic leptospires can survive free in the environment, depending on soil type and geologic factors in moist conditions such as in soil, mud, swamps, drains, surface waters, streams, and rivers, as long as conditions are not acid.[58] All of these sites are well known as sources of leptospirosis.[5,36] The leptospires can infect fresh host animals or humans via broken skin or mucosal surfaces.

Food preparation areas can be contaminated by infectious urine from foraging carrier rodents, resulting in infections in food process workers. Urine splash and aerosols can infect milkers (especially in "herringbone"-pattern milking sheds), veterinarians, and animal handlers. Animal tissues and blood are infrequently causes of leptospirosis, more often so in workers, inspectors, and transporters of meat. Conception products and autopsy of infected livestock and

separated kidneys used for domestic food can transmit leptospirosis to veterinarians, farmers, laboratory workers, and food-handlers and cooks.

Numerous outbreaks associated with water have been reported.[70] Spread of leptospirosis is not known to occur by airborne, respiratory, or gastrointestinal routes. However, immersion in, or ingestion of, water is a risk factor in other outbreaks[22,91] and it seems probable that leptospires can penetrate the oral or nasal mucosa. Human-to-human transmission is virtually unknown, apart from in utero congenital infection.

Laboratory-acquired infections usually have resulted from accidents involving direct skin penetration with cultures or suspensions of infected tissues via syringe and needle, broken glass, or splash into an unprotected eye, and from being bitten by infected animals (usually rats) whose urine contaminated the bite.

Leptospires die rapidly when dry. Drying out of surfaces or environments contaminated by infective material prevents spread, even after rehydration. Heating above about 42°C is lethal to leptospires, but they survive freezing.

7. Pathogenesis and Immunity

7.1. Incubation Period

The incubation period of leptospirosis varies from 2 to 21 days, usually between 3 and 10 days, although longer periods have been reported. It is relatively shorter with larger infective doses or more virulent leptospires. Incubation periods can be calculated from a recognized infection episode, but they are difficult to define when there is continual or repeated exposure. The relatively sudden onset makes it easier to detect the first clinical symptoms unless they are very mild or unnoticed. In these cases the incubation period may be erroneously dated to the onset of late presenting symptoms such as hemorrhage, meningitis, or renal failure.

7.2. Virulence and Its Attributes

The mechanisms by which leptospires cause disease are not well understood. A number of putative virulence factors have been demonstrated, but with few exceptions their role in pathogenesis remains unclear. Toxin production and adhesion have been shown by some strains in vitro and in vivo. Surface antigens clearly play an important role in virulence. The lipopolysaccharide (LPS) of leptospires is only weakly endotoxic. Early studies demonstrated the importance of LPS as a target of the immune response,[50] and recent data suggest that the O antigen content is modulated in acute versus chronic infections.[93] Much recent work has focused on the role of surface lipoproteins as potential virulence factors.[31] Many of the surface exposed lipoproteins such as OMPL1, LipL21, LipL32, LipL41, LipL45, and LipL46 are up-regulated in vivo, while others such as LipL36 are down-regulated.[82,94] LigA and LigB are adhesins, the expression of which is induced by physiological osmolarity.[27,81] Other adhesins have also been described recently.[9]

Genomic analysis has shown the existence of several hemolysins in *L. interrogans*.[145] Lk73.5 is a host-inducible sphingomyelinase in *L. interrogans* that is not produced in vitro.[7] LipL32, the predominant surface protein, is a hemolysin.[15] LruA and LruB are inner membrane lipoproteins that share epitopes with equine corneal proteins.[127] IgG and IgA antibodies to these proteins are found in uveitic eye fluids. Other proteins have been shown to bind factor H and this contributes to serum resistance.[85,128]

7.3. The Course of Events in Infection

7.3.1. Entry. Leptospires gain entry through small abrasions or cuts in the skin or mucosal surfaces. Entry may occur via the conjunctiva or by aerosol into the lungs, as well as by inhalation following immersion in contaminated water. As described above, ingestion of water probably results in penetration of the oral or nasal mucosa. Laboratory infections have occurred through injections, needle-stick injuries and cuts, and eyesplash accidents.

7.3.2. Spread. Leptospires that enter the body spread at once in the lymphatics and bloodstream. There is no initial localizing acute inflammation at the site of entry. Leptospires can be found distributed in various tissues within 2 h of infection. Both TLR-2 and TLR-4-dependent mechanisms appear to be important in the activation of the innate immune system.[134,139] Nonpathogenic leptospires and avirulent strains of the pathogenic species of *Leptospira* are opsonized by innate serum IgM. All leptospires may be opsonized by specific immune IgM or IgG in hosts previously immunized by infection or vaccination. Phagocytosis occurs rapidly in reticuloendothelial fixed phagocytes in the liver (Kupffer cells) and lung. These phagocytes later migrate to the spleen. The bloodstream is cleared rapidly following opsonization, which may occur with minimal detectable levels of immunoglobulin recognized as agglutinating antibody. Polymorphonuclear and mononuclear phagocytes can be observed to take up leptospires from the tissues following the development of antibody.

In the absence of immunity and consequent phagocytosis, leptospires grow in the body in an initial infection as if in culture. Nothing is known of specific nutritional requirements in vivo. Both virulent and avirulent leptospires

have been shown to adhere to fibroblast-derived cells in the laboratory.[8]

A threshold level of leptospires is required in the blood before lesions occur. In severe leptospirosis approximately 10^4 leptospires per ml blood are associated with a poor outcome.[107,123] The first and most important lesions to be detected are in small blood vessels throughout the body. Localized endothelial cell degeneration occurs, followed by small localized extravasations that frequently contain leptospires.

Fever occurs at an early stage of infection. At this stage it is also possible to demonstrate microscopic focal degeneration of skeletal muscle fibers, notably in the calf muscles. The extreme pain in muscles and acute tenderness found clinically are presumably the result of these lesions. Thus, the main presenting symptoms of severe headache, fever, and muscle pains can be attributed to the effects of leptospires growing in the body to threshold levels sufficient to cause characteristic damage to small blood vessels.

The natural history of the further development of leptospirosis in either humans or animals is similar. Exponentially increasing numbers of leptospires lead to severe blood vessel damage, local ischemia, and small hemorrhages in most tissues, and eventually to major organ damage. Depending on the serovar of leptospire, there is greater or lesser hepatocellular degeneration, leading to jaundice; renal tubular degeneration similar to that seen in crush injuries or after renal ischemias, leading to an acute, often hemorrhagic interstitial nephritis; and pulmonary hemorrhages ranging from insignificant to gross and fatal, with hemoptysis. Cholecystitis, symptoms of acute abdominal emergency, meningitis, hemiparesis, myocarditis, adrenal hemorrhage, and placentitis have all been reported.

7.3.3. Lesions. Once the infection is fully developed, the typical lesions described in clinical–pathological and postmortem studies of leptospirosis, usually of the severe and fatal types, appear. Hemorrhage is associated with a sudden drop in platelet numbers, possibly as a result of leptospiral toxin action or of adhesion of leptospires. The potential role of disseminated intravascular coagulopathy syndrome is not clear.[39] Anemia is common, usually not as a result of hemorrhage alone. Evidence of nitrogen retention is found almost universally, albeit transitorily, reflecting the renal ischemia occurring even in mild types of leptospirosis. In these cases, patients whose kidneys are functioning poorly and at the limit of compensation due to other causes of renal insufficiency may be precipitated rapidly into renal failure. In severe cases there is very widespread tubular degeneration, which is the usual main cause of death. Other potentially fatal lesions include hepatocellular degeneration, pulmonary hemorrhages, and myocarditis.[6,34,35]

7.3.4. Transplacental Spread. Transplacental infection can occur at any stage of leptospirosis. If the fetus or placenta is severely damaged, abortion will occur. Stillbirth or congenital leptospirosis may follow infection late in pregnancy. Abortion is a well-documented cause of loss of productivity of livestock. In human congenital infection, IgM antibodies can be demonstrated in the fetus and cord blood and leptospires in the degenerative lesions in tissues.[50]

7.3.5. Recovery. Recovery from leptospirosis commences as soon as the patient produces opsonizing antibody, which leads to rapid phagocytosis of leptospires in the circulation and in the tissues. Mopping up phagocytosis also follows destruction of leptospires by antibiotics. Opsonizing antibody levels can be correlated with agglutinating antibody levels. Virtually any detectable specific agglutinating antibody in MAT can signify opsonic activity. Bacteriologic clearance of live leptospires from tissues by antibody, however, does not ensure clinical recovery, especially in severe leptospirosis, because lesions in organs and tissue damage may have proceeded to stages where vital functions are almost irreversibly impaired. Clinical supportive measures for renal failure (dialysis), hemorrhage (transfusion), myocarditis, and liver failure may be necessary until the patient's tissues regenerate. Complete recovery is the rule in surviving patients, although rare examples of prolonged asymptomatic renal carriage have been recorded in people.

7.3.6. Carrier State. The carrier state occurs very rarely, if at all, in humans. This is assumed to result from the acidic reaction of human urine. In animals it follows recovery from systemic infection, which may be subclinical. Leptospires are attached to the epithelial surface of proximal renal tubule cells, where they grow in the tubular lumen and are excreted in the urine. Homologous antibody may be demonstrated in the urine of carriers. Active excretion may be sporadic or intermittent. The mechanisms of adhesion, immunologic events, and nutritional needs of leptospires in renal tubules need to be elucidated. There is no inflammation around affected tubules, which appear to be morphologically intact in electron microscopic studies. In some animals (especially dogs and pigs) there may be considerable scarring in the kidneys where leptospires occupy renal tubules, apparently related more to the recovery and repair processes following renal damage (acute nephritis) and hemorrhage in the acute state of infection than to the presence of leptospires in the tubules. Leptospires are not found in renal tissue outside renal tubules in carrier animals. Genital carriage of leptospires has been described in livestock.

7.3.7. Autoimmunity and Hypersensitivity. The roles of autoimmunity and hypersensitivity in producing lesions are unclear. The acute nature of infection and absence of chronic infection precludes consideration of

these immunopathologic mechanisms in the development of initial lesions. However, leptospires may be sequestered in "privileged sites" during acute infection, leading to later allergic reactions to their presence. A notable example is uveitis that has followed either systemic infection or accidental laboratory inoculation into the conjunctiva. Leptospires may be cultured from the anterior chamber of the eye for long periods after infection. Contact with leptospiral antigen can cause an allergic aggravation of the uveitis. A similar condition known as equine recurrent uveitis or "moon blindness" occurs in horses and results from antigenic mimicry between epitopes on equine cornea and an antigen expressed by some *Leptospira* serovars associated with equine uveitis.[77]

7.4. Immunity

7.4.1. Specific and Nonspecific Immunity. Low levels of innate antileptospiral IgM antibodies, found in the serum of humans and other animals not known to have been exposed to leptospirosis, destroy avirulent leptospires but are inactive against virulent strains. Nothing is known of nonspecific immunity to leptospirosis stimulated by infection with other bacteria or their LPS.

Specific immunity to leptospirosis develops rapidly, within a few days of clinical or subclinical infection. Fully effective immunity can be transmitted passively naturally through the placenta and colostrum and artificially with convalescent or hyperimmune serum. Both IgM and IgG antibodies are protective, and presumably colostral IgA antibodies are also, although there is no direct evidence. Immunity is associated with agglutinating antibodies which are also opsonic; moreover, a very low level of agglutinating antibody is protective. Immunity to reinfection is specific for the infecting serovar or closely antigenically related serovars, almost exclusively within the same serogroup determined by MAT.

Some animal species are relatively resistant to leptospiral infection with certain serovars; the basis of such resistance is unknown. It is not known whether humans are incapable of infection with any serovars. Generally, young animals are much more susceptible than old, provided they have no maternally endowed passive immunity. The development of age-related relative resistance to leptospirosis reflects the rate of maturation of the B-cell immune response.

The humoral immune response induced by immunization protects against disease but not against infection and subsequent renal shedding. Cell-mediated responses occur following infection and following immunization with newer vaccines[92]; there appears to be a lower degree of cell-mediated immunity following natural infection. In contrast to the traditional vaccines, cattle immunized with these vaccines are protected against renal colonization and urinary shedding.[13] Recent evidence suggests that a Th1 immune response also occurs in humans.[66,129]

The duration of immunity in humans is not known. Agglutinating antibodies fall in titer after infection, but the rate is very variable in individuals and there are no studies of the relative rates of fall of IgM and IgG antibodies. Some people known to have had leptospirosis are seronegative in 1 or 2 years and others are still seropositive after more than 10 years, although the possibility cannot be excluded that they have had continued exposure to leptospires during this period.[33,44] It is not clear that the loss of detectable agglutinating antibody over time following infection is synonymous with loss of immunity. These deficiencies in knowledge are obviously important for understanding immunity, epidemiology, and planning for vaccines.

7.4.2. Antibodies. Convalescent sera contain specific IgM, IgG, or both. Usually, IgM is elaborated first, within approximately 7–20 days of infection, followed by IgG. In some patients, seroconversion does not occur until 30 days or more after onset of infection. IgM persists at low levels in certain cases, while in others IgG is sometimes the sole demonstrable immunoglobulin. However, information from this type of retrospective study is necessarily limited in value because one cannot know for certain beforehand the previous history of exposure to leptospirosis. Cross-reactions with related and occasionally with unrelated serovars occur, especially early in infection. These "paradoxical reactions" occur typically, for example, between serovars Icterohaemorrhagiae and Canicola, and Icterohaemorrhagiae and Pomona. IgG antibodies tend to be more specific. In some patients treated very early with penicillin whose infections were proved with blood cultures, seroconversion did not occur at all or was delayed several weeks. Antibodies to the infecting serovar may be found in the urine of carrier animals.[50]

7.4.3. Antigens Related to Pathogenesis and Immunity. Antibodies reacting with antigens in flagellar, subsurface, and outer-envelope locations have been identified in sera from patients who have been proved to have leptospirosis. Some of the antibodies persist for months and years.[11,33,78]

7.4.4. Vaccines. Vaccines for leptospirosis were introduced soon after leptospires were identified and could be cultivated. Preparations effective in protecting animals and humans have been made by killing the leptospires in cultures with heat or formalin and injecting doses subcutaneously or intramuscularly. Formalin-killed cultures are used widely to vaccinate animals (cattle, pigs, dogs) and are in use in some countries to vaccinate people. The vaccine is usually given subcutaneously in two doses and repeated

annually. There is a high incidence of painful swellings at the injection site, especially on revaccination.

In countries where leptospirosis is confined to clearly recognized occupational groups whose source of infection is livestock, the vaccination of livestock is recommended and used widely to decrease shedding by carrier animals with the twofold purpose of reducing and eliminating animal leptospirosis, thus increasing productivity, and protecting humans at risk from unavoidable exposure to these animals. Pregnant sows are commonly vaccinated to ensure passive protection to growing piglets. However, piglets may acquire asymptomatic leptospirosis after their passive protection has been lost, and they may then become shedders and thus a hazard to handlers, slaughtermen, and other abattoir workers.[23] Similarly, cattle that have been vaccinated are protected against disease but not against infection. The major limitation to use of vaccines in dogs is the potential for infection with serovars that are not included in the vaccine. Vaccinated dogs may thus represent a source of human infection.[47,53]

More recently a new generation of vaccines have been introduced that induce cell-mediated immunity in cattle.[19,92] Moreover, immunization with such vaccines prevents both disease and urinary shedding.[13]

8. Patterns of Host Response

Several epidemiological features of leptospirosis determine the host responses and clinical features. The disease is almost uniquely acquired from carrier animals, which cannot be identified as carriers or shedders without laboratory tests. Inapparent infections in humans are not relevant to clinical disease or transmission.

The severity and presenting features of clinical leptospirosis result from a complex of climatic, social, and geographic factors influencing the animal host and source, and thus the serovar and the clinical features and in turn the accuracy of diagnosis and notification. In general, different leptospiral serovars are associated with characteristic groups of animal species.

Living conditions for most people in tropical countries favor contact with rodent sources of leptospires rather than other animals. Most of the leptospires that clinically result in the very severe leptospirosis of the classical Weil's disease type, which may be fatal following renal failure, hemorrhages, and jaundice, are carried by rats. Serovars of the Icterohaemorrhagiae, Autumnalis, and Bataviae serogroups are examples.

Conversely, in temperate climates, in addition to rats, there are other carriers of leptospires such as field mice, pigs, dogs, and cattle that shed mainly leptospires of those serovars causing a milder form of illness. The disease also tends to be much more occupationally related and confined to people in contact with these animal sources. Serovars Grippotyphosa, Hardjo, Pomona, and Tarassovi are examples of this group.

Perceptions and statistics of leptospirosis are influenced by whether the disease is seen as the severe or the mild type. Mild infections of either variety have often been overlooked because the symptoms are not pathognomonic. Usually, seriously ill patients who needed hospital treatment or died were accurately diagnosed as leptospirosis. Since they were the only ones in whom the diagnosis was made, the clinical features recorded and reported in textbooks have been those of the severe type, emphasizing jaundice, hemorrhages, renal failure, meningitis, and a high case-fatality rate. Overall, these symptoms appear in only a few and late cases of the classical syndrome of Weil's disease. Most patients affected with any serovar report initial symptoms as described below. The severe and the mild types differ in their subsequent progress.

8.1. Clinical Features

The clinical features are usually divided into the mild anicteric phase,[10] accounting for about 90% of all cases, and the severe or icteric disease causing the syndrome Weil's disease.[41] Characteristically, leptospirosis commences suddenly with headache, myalgia, fever, and red eyes. Headache develops without warning and may be extremely severe. Myalgia is usually felt in the back and especially in the calf muscles, which may be excruciatingly tender to touch. The fever is generally greater than 39°C and the red eyes are the result of conjunctival suffusion, reflecting a generalized dilation of blood vessels, rather than a conjunctivitis. There is frequently a macular rash on the trunk, lasting only a few hours. Careful examination of the palate may show a similar petechial rash. In untreated patients with the mild type of leptospirosis, the symptoms usually persist for 3–10 days, followed by gradual but complete recovery. Occasionally, further acute symptoms may develop. These include oliguria from renal failure; acute abdominal pain, resembling an acute abdominal emergency and sometimes due to acute cholecystitis or pancreatitis; meningism, hemiparesis, or other neurological signs; and cough, sometimes with mild hemoptysis. Jaundice is rare in mild-type leptospirosis. Aseptic meningitis may develop as a later complication, but most patients recover fully within 3–6 weeks.

In patients with severe leptospirosis, the symptoms increase in severity, at times following a 1- or 2-day temporary remission. Delirium and confusion may develop, with increasing evidence of renal failure, together with hemorrhages and jaundice. In addition, the spleen may be enlarged.

Pulmonary hemorrhages may be diffuse, resembling multiple infarcts or bronchopneumonia, accompanied by coughing of blood, but in some cases the pulmonary hemorrhages and hemoptysis may be gross. Adult respiratory distress syndrome can also occur and cause death. As liver and renal failure progress, jaundice and oliguria increase, confusion and delirium give way to unconsciousness, and death occurs through renal and hepatic failure. Supportive measures such as dialysis can tide patients over renal failure until renal structure is regenerated and function restored. Myocarditis, evidenced by arrhythmias, can cause sudden death. Final recovery is usually complete unless vital organs are irreparably damaged. The earlier severe phase is described as the septicemic stage and the later the tissue phase.

Death from renal failure may occur at any state of the illness. The autopsy appearances will depend on the duration and degree of development of lesions. Usually, there is generalized jaundice and widespread hemorrhage in the skin, muscles, peritoneal surfaces, and lungs. The kidneys are enlarged, bile stained, and have subcapsular hemorrhages. Bleeding into all viscera including the adrenals is common. The liver shows signs of hepatitis and hemorrhages. Death is so rare in mild cases that there is no record of significant and characteristic autopsy appearances. Uveitis may develop at any time after the second week, and as late as 6 months. It may affect one or both eyes.[80]

8.1.1. Congenital Leptospirosis. Leptospirosis in pregnant women can be transmitted to the developing fetus at any state of pregnancy.[28,52] The fetus is actively infected. If it is severely damaged, even by serovars causing the mild type of leptospirosis in the mother, it may die.[3,29] If infection occurs near the time of birth, the child may develop congenital neonatal leptospirosis, whose manifestations are similar to those of adult leptospirosis. Complete recovery follows satisfactory treatment. The diagnosis of intrauterine leptospirosis depends on the correct diagnosis in the mother and evidence that the fetus is infected as shown by fetal distress. Antenatal proof is usually only available if the fetus dies. If the fetus recovers before birth, IgM antibodies will be present in the cord blood. The diagnosis of neonatal congenital leptospirosis involves the same methods as used in adults.

8.1.2. Clinical Laboratory Findings. Laboratory tests, other than bacteriologic or serological, may help support the clinical diagnosis. In the absence of bleeding, the erythrocyte count and hemoglobin may be normal unless the patient is jaundiced, and then they are both reduced. Leukocytosis of 11–20,000/mm^3 (11–20 $\times$ 10^9/liter) is usual in icteric patients. The platelet count is frequently reduced, especially in severely jaundiced patients. The erythrocyte sedimentation rate is generally raised.

Blood urea and creatinine are frequently raised, at least transiently, even in mild cases. Liver function tests are useful diagnostically. The serum aminotransferases can be normal or mildly elevated. The aminotransferases are usually below 250 I.U./L and are seldom greater than 500 I.U./L. The serum bilirubin level is always raised in icteric or preicteric leptospirosis. The combination of raised blood urea, raised direct bilirubin, and normal or slightly elevated aminotransferases serves to differentiate leptospirosis from hepatitis in which the serum aminotransferases are always significantly elevated.[41]

Proteinuria is a constant but sometimes transient finding, even in mild cases. In severe cases, or wherever there is renal failure, granular and hyaline casts will be found in urine, together with bile.

Examination of CSF reveals a leukocytosis and increased protein with normal glucose.

8.1.3. Prognosis. Recovery is usually complete within a few weeks in mild-type patients. However, residual depression, irritability, and psychosis have been reported, lasting up to 6 months and preventing a return to normal life and work. Occasional reports of prolonged headache and backache following mild leptospirosis are hard to evaluate. Patients who survive the severe type of leptospirosis usually show no further signs of illness within a few weeks of full recovery of function in vital organs. Prolonged neurological symptoms and signs have been recorded, but in some of these patients there is room for doubt about the validity of the original diagnosis. In the severe disease mortality ranges from 5 to 25%.

8.1.4. Treatment. Penicillin (or erythromycin in allergic patients) is the recommended treatment of choice as early as possible in the illness.[38] Doxycycline [83] or a third-generation cephalosporin are also used.[97,117] Given on the first day or two in patients diagnosed in the acute stage of infection, it can abort the symptoms and progress of either the mild or the severe form abruptly, so that the patient is frequently clinically well within 24 h.

Antibiotics given in the late ("tissue") stages may make no difference to the outcome,[30,40] because the disease process is then a consequence of established lesions, the leptospires usually having been eliminated by the patient's development of antibodies. However, most clinicians would give patients the benefit of the doubt and administer intravenous penicillin, cefotaxime, or ceftriaxone. A Jarisch–Herxheimer reaction (temporary aggravation of symptoms and fever) may occur when antibiotic treatment is commenced in well-advanced patients,[54,126] but this should not prevent the initiation of antibiotic treatment.[138]

In severe cases, symptomatic and supportive systemic treatment is required for hemorrhage and shock. Meticulous

attention to fluid and electrolyte balance is critical. Renal failure may be treated by peritoneal dialysis, hemodialysis or continuous venovenous hemofiltration. There is no specific therapy for the hepatic insufficiency. Patients with arrhythmias and myocarditis should be monitored in an intensive care environment and the various arrhythmias treated. Severe pulmonary hemorrhage may require assisted positive pressure ventilation.

8.2. Diagnosis

8.2.1. Clinical Diagnosis. The clinical features in early leptospirosis of either the mild or the severe type are not pathognomonic and give no indication of the diagnosis to an inexperienced clinician. In areas where the disease is common and has been recognized using laboratory confirmation, fresh cases can be diagnosed with a high degree of accuracy, provided that there is not a concomitant outbreak of a similarly presenting disease at that time e.g., dengue fever.[73,106]

Epidemiological factors such as occupational or domestic exposure to risk of infection from carrier animals, recent exposure to fresh water with immersion, or recent travel will influence the interpretation of clinical findings, pending results of confirmatory laboratory tests.

8.2.2. Laboratory Bacteriologic Diagnosis. The principles of diagnosis are isolation of leptospires from blood, urine, CSF, or other sites during the acute illness, demonstration of leptospires in tissues and body fluids, and serological tests. Because of the low index of suspicion combined with the perceived difficulty of culturing leptospires, most cases are diagnosed by serology.

8.2.2.1. Diagnosis by Direct Detection of Leptospires. Leptospires can be seen occasionally in body fluids by dark-field illumination. Inexpert observers looking at body fluids can mistake fibrin threads for leptospires. Dark-field microscopy is neither sensitive nor specific enough for diagnostic use.[131] Leptospires may also be identified directly by staining of smears, or of frozen or wax-embedded histological sections of autopsy or biopsy material. Molecular diagnosis of leptospirosis is discussed above.

8.2.2.2. Culture. Diagnostic cultures are usually made from specimens of blood, urine, CSF, other body fluids and exudates, and occasionally from tissues obtained at biopsy or autopsy. Tween–albumin fluid culture media such as EMJH are most generally useful, because more exacting strains grow better in it on primary isolation. Special media are required for primary isolation and growth of fastidious pathogens.

Blood cultures are made by inoculating blood drawn aseptically by venipuncture directly into culture media. Inoculation of several tubes, each containing 5–10 ml of medium, with one or two drops of blood per tube (up to 250 μl per tube), is recommended. The blood should be diluted in the culture medium by a factor ofat least one in ten in order to dilute antileptospiral activity in the blood. If blood cannot be inoculated at the bedside, it can be collected in a sterile ammonium oxalate or heparin anticoagulant tube or even as a last resort in a plain tube and transported to a laboratory, where the blood or serum can be inoculated into medium. If possible, multiple cultures should be prepared from each specimen. Penicillinase and sodium polyanetholesulfonate (SPS) can be added if required. The inoculated media are incubated at 30°C and examined for growth by dark-field microscopy daily for the first week and weekly thereafter, up to 3 months, and ideally they should be subcultured weekly. The value of blood culture is definitive identification of the etiological agent rather than speed. Isolates may be identified by serological or molecular methods as described above.

Culture of urine requires an alkalinized fresh midstream or catheter specimen taken with care to minimize contamination. A selective medium containing 100 μg/ml 5-fluorouracil as an inhibitor of contaminant microorganisms and semisolid medium containing 0.1% agar are recommended, using at least a tenfold dilution of urine in the medium. Multiple cultures should be prepared from each specimen.

Leptospires may be found in CSF in the first 10 days of illness and can be cultured from it by inoculating 0.1–0.5 ml into 5–10 ml of fluid or semisolid culture medium.

8.2.2.3. Serological Diagnosis. Even if cultures are set up, recovery of leptospires requires weeks, rather than days, of incubation. Moreover, the diagnosis of leptospirosis is often not suspected, or the patient does not seek medical attention until the illness is well advanced, when leptospires be difficult to recover. Thus, serological tests may be the most reliable means by which a retrospective, if not concurrent, diagnosis can be made.

Both IgM detection by ELISA and detection of agglutinating antibodies by MAT are useful for diagnosis. Serum specimens for diagnosis by serological tests should be taken immediately at the outset of investigations, preferably on the first day of illness, and tested as soon as possible. A further specimen should be taken on the fifth to seventh days, and further tests if required on the 10th and 12th days. IgM antibodies are detectable 5–7 days after onset of symptoms, thus sensitivity of IgM detection is low during the first week of symptoms, rising rapidly after that.[32] Early in the illness, detection of IgM is significantly more sensitive than the MAT. A positive IgM should be followed by MAT testing of acute and convalescent specimens for confirmation by rising antibody titers.

8.2.3. Differential Diagnosis. At the onset of either mild or severe leptospirosis, there is little to distinguish it from any other acute febrile illness. The very severe headache, fever, and myalgia are characteristic, but at this stage they may be confused with severe influenza, poliomyelitis, dengue, Q fever, and viral meningitis. The main differentiating criteria in leptospirosis are raised blood creatinine and urea, leukocytosis, and in some cases, an early rise in titer of leptospiral antibodies. At a later stage the main differential diagnoses are with viral meningitis and acute abdominal emergencies in mild-type leptospirosis and with malaria, blackwater fever, viral meningitis, hepatitis, yellow fever, hemorrhagic fever with renal syndrome (HFRS) and acute glomerulonephritis in severe leptospirosis. The main diagnostic criteria are high serum bilirubin with low or normal levels of serum aminotransferases, thrombocytopenia, and renal insufficiency with significant and rising titers of specific antileptospiral antibodies. The isolation and identification of leptospires from blood, urine, or CSF, or a positive PCR assay, confirm the diagnosis. At autopsy, differential diagnosis depends on characteristic pathological changes of jaundice and widespread hemorrhages with pale, enlarged hemorrhagic kidneys showing histological evidence of renal tubular degeneration and hemorrhage, liver cell degeneration, myocarditis, and pulmonary hemorrhages. Postmortem serum specimens may be tested for antibodies. PCR and IHC testing of autopsy specimens are sensitive, particularly in patients who die of fulminant disease before they seroconvert.[17]

In all patients, an epidemiological history of occupational or accidental exposure to risk and animal contact or travel should increase the index of suspicion and indicate the need for specific diagnostic tests.

9. Control and Prevention

9.1. General Concepts

As is the case in all zoonoses, control of leptospirosis in humans is complex, because the primary sources of the disease are in animals, in some of which control is impossible. Regulation if not elimination of leptospirosis may be feasible in livestock and domestic animals, even though carriers are clinically normal and shedders hard to detect, but it cannot be envisaged in wildlife. Control is further complicated by the general and nonspecific clinical picture of mild or early severe leptospirosis, indistinguishable from a variety of other incapacitating fevers common in tropical areas, so that an animal source is often not suspected. The essentials of control and prevention lie in awareness and recognition of the disease and in containment in livestock and domestic sources.

Awareness and recognition require a knowledge of epidemiological facts acquired by selected surveillance, reporting, and notification, which in turn need specialized diagnostic laboratory services and education of physicians, veterinarians, administrators, and the public. Although containment of animal sources may be seen as a veterinary public health and hygiene problem, it is essential to the protection of humans. The main measures are veterinary surveillance, treatment, and prevention; occupational hygiene; rodent control; engineering; laboratory safety; and evaluation of preventive measures. In addition, containment extends to the prevention of human disease by the judicious avoidance of risk, by immunization, and by chemoprophylaxis.

9.1.1. Education, Laboratory Services, and Notification. Ordinary routine microbiological diagnostic laboratories are not usually equipped with skilled staff and specialized techniques for leptospirosis. If specialized diagnosis is not available locally, there should be a central leptospirosis laboratory available for referral of specimens and consultation. Reference laboratories staffed by experts are required only on a regional international basis for stock cultures, standard sera, research, education, and consultation. New methods of molecular diagnosis may make diagnostic facilities more readily available.

Evaluation of diagnostic laboratory results provides a useful form of surveillance. In addition, prevalence surveys for antibodies in selected groups can reveal problems or evaluate control measures. The most effective form of information gathering should be notification by health practitioners. Usually, this is of limited value because of inadequate diagnosis, failure to use appropriate laboratory tests, and failure to notify. Statistics of practitioner notifications frequently indicate an incidence much lower than diagnosed by laboratories.

9.1.2. Control Measures in Animals

9.1.2.1. Rodent Control. Removal of rodents from the domestic environment effectively reduces the infection rate of leptospirosis. Standard measures include control of litter and garbage disposal, protecting food sources, trapping, and poisoning. When they share the environment with crops, precautions can be taken, such as burning off sugarcane before cutting by hand or mechanization of cutting.[50]

9.1.2.2. Environmental Control. Any measure to reduce the load of leptospires in soil, water, or mud will reduce the risk to humans. Simple drainage can prevent seepage of urine into waterlogged soils or yards where livestock are herded. Environmental engineering can also increase the risk by flooding previously dry areas.

9.1.2.3. Immunization, Chemotherapy, and Culling of Livestock. Excreter rates in cattle and pig herds frequently reach levels of 65–90%. If shedders can be identified and removed from herds, the risks to the herd and to attendant humans can be reduced, provided the remaining animals are immunized, the herd is restocked with immunized animals, fresh excreter animals are not introduced, and the herd is protected from fresh infection from environmental sources. Immunization alone can reduce both animal and indirectly human leptospirosis, but it is hard to evaluate, because most studies have been specially set up under artificial conditions accompanied by education and improvements in occupational hygiene and farming practice. Culling or vaccination is both expensive and their use by small holding farmers will depend on the relative values and costs of animals, vaccines, and health (or illness). The associated costs of transport, skilled attention, and equipment may also be relatively high. The control of leptospirosis in stud stock, where leptospires may be found in semen samples used for artificial insemination, requires special methods for testing and transport of semen.

9.1.3. Treatment of the Carrier State. Carrier animals have been cured by streptomycin treatment. The cost is relatively high and the results so difficult to evaluate in field conditions that it is considered impractical for general use.[43,56]

Humans do not become chronic carriers or excreters for any length of time. Elementary domestic, personal, and hospital hygiene ensures little risk from patients and convalescents still excreting leptospires. Urine specimens from convalescent patients are not recognized sources of laboratory infection, but care should be taken nonetheless.

9.1.4. Occupational Hygiene. Preventive measures for people who cannot avoid exposure to risk are centered around methods for physical protection in their work or leisure. Waterproof footwear, watershedding aprons worn outside and over the boots or other clothing, and clear plastic facemasks have all been recommended for milkers and slaughterhouse workers. In hot climates or working conditions, impermeable protective clothing is uncomfortable and poorly accepted. Nevertheless, rubber boots provide obvious protection. Wearing of gloves by field workers, such as cane cutters, is also protective. Most infections appear to follow penetration of cuts and damaged or abraded skin by leptospires. It is therefore important to protect such injuries, but often not practicable to do so in daily working conditions.

Good drainage of floors and herding yards and control of rodent infestation in food preparation areas are important occupational hygienic measures, but no measures will be effective unless the people at risk understand the disease, the means of infection, and the need for precautions so that they are prepared to implement recommended practices. The risk for field workers can be reduced by attempting to control the environmental hazards.

9.2. Antimicrobial Prophylaxis

Chemoprophylaxis with doxycycline has been used to prevent leptospirosis in soldiers exposed to jungle conditions[119] and could be used similarly to protect anyone exposed to a significant risk for a brief defined period. People in such categories could include those about to undertake rafting or canoeing trips, cavers, grain farmers and workers at harvest time when risks are serious for a short period only, and field ecologists trapping small wild rodents. Doxycycline prophylaxis of large populations after severe flooding has not been shown to be effective for preventing infection,[57,108] but may reduce the incidence of clinical disease.

9.3. Immunization

Immunization of humans and animals with killed cultures of leptospires has been used almost since leptospires were discovered. Vaccines are serovar specific and currently administered subcutaneously in two or more doses 2 or 4 weeks apart and repeated annually. Vaccines for human use are licensed in France, Cuba, and several Asian countries.

Local reactions of pain, redness, and swelling ranging from mild to very severe occur, especially on revaccination. Washed or whole culture vaccines have been employed in several countries, mainly in Asia, where the risks to life and health from severe leptospirosis could justify the side effects of the vaccine.

10. Unresolved Problems

There is a series of interconnected questions that need answers before great improvements in control of leptospirosis can be achieved. Neither the duration of postinfection immunity nor its specificity is known. Conventional wisdom based mainly on animal experimentation states that immunity is specific for antigens that are serovar specific, or at best shared within a serogroup. Is there any underlying genus- or species-specific immunity in humans mediating a level of resistance to all serovars of pathogenic leptospires?

There are genetic differences in the susceptibility of pigs to primary infection. At least one study from an outbreak suggests that human susceptibility may be under genetic control.[76] Can this study be generalized, and if so, are the differences reflected in the response to particular serovars or to all serovars, and thus to the pathogenicity of particular serovars for humans?

There are over 250 serovars described among the pathogenic leptospires, based on antigenic surface characteristics mediated by LPS-related polysaccharide epitopes. Although part of the LPS gene has been characterized, the genetic basis for serovar specificity and variation is still unknown. This problem becomes acutely relevant with the recognition that the various species of *Leptospira* each contain serovars also found in other species; that is, serovar specificity overlaps the genetic groupings. Moroever, mosaicism within several genes suggests horizontal transfer.[60] The effects of these observations on classification of leptospires have implications for diagnosis, epidemiology, and prognosis. Many more isolates need to be genotyped, but to do this will require more easily applied methods.

Rapid bedside tests are required that will enable a clinician to identify whether or not a patient has leptospirosis, and if so, which serovar, often at a time in the illness before antibodies have appeared in blood. Direct tests for leptospires or their antigens would overcome the serious difficulty of evaluating the significance of a positive serological test in a patient in an endemic area where most of the population have antibodies, even residual IgM, to one or more serovars, or where the patient may have residual antibodies from an infection with a serovar unrelated to the present illness. Similar direct diagnostic methods would allow easier and more positive detection of carrier animals than is possible now.

Most people at risk from leptospirosis live in developing countries without ready access to specialized diagnostic or treatment facilities. There is seldom a capacity for new scientific research into the problems identified here. On the other hand, leptospirosis is rarely diagnosed in urban agglomerations in developed countries where most researchers and institutes capable of high technology are found and there are relatively few among them interested in leptospirosis. Knowledge and research in leptospirosis are thus not available in most developed countries, to which developing countries turn for scientific assistance. The situation is aggravated when inadequate statistics in developed countries indicate a spuriously low rate of leptospirosis, leading to an impression that the disease is nonexistent or unimportant and does not justify allocation of funds for the maintenance of existing research and surveillance or for new studies toward solutions to the problems outlined above.

CHAPTER 22

Listeria monocytogenes Infections

Donald Armstrong and Donald B. Louria

1. Introduction

Listeria monocytogenes has been recognized as a human pathogen since the turn of the nineteenth century. Investigations of listeriosis epidemics in North America and Europe over the past 25 years have confirmed a long-held suspicion that listeriosis is a foodborne disease.[1–7] *L. monocytogenes* infections resulting in invasive disease occur particularly often in the immunocompromised host, specifically those in whom the T-helper cell−mononuclear phagocyte arm of the immune defense system is altered. Severe disease also occurs in the very young and in older persons as well as in patients with neoplastic disease and in recipients of organ transplants. Alcoholism, cirrhosis, and diabetes mellitus are also frequently associated risk factors, as are adrenocorticosteroid therapy for underlying disorders such as collagen vascular disease or inflammatory bowel disease and treatment of certain chronic diseases with tumor necrosis factor alpha (TNF_alpha)-neutralizing agents.[8–11] Although not a common opportunistic infection among patients with advanced human immunodeficiency virus (HIV) infections, listeriosis has been shown to be at least 100 times as frequent in acquired immunodeficiency syndrome (AIDS) patients than in the general population.[12,13] *L. monocytogenes* has a predilection for pregnant women, with potentially lethal consequences for the fetus in utero and the newborn. Normal hosts are not entirely resistant to invasive infections, and the occurrence of listeriosis in such individuals should not warrant an exhaustive search for an underlying but yet undiagnosed immunosuppressive disorder.

In immunocompromised and elderly adults (nonperinatal listeriosis), the clinical presentation is usually sepsis or meningitis, or a more subtle nonmeningitis central nervous system (CNS) infection such as meningoencephalitis, cerebritis, or brain abscess. While these severe forms of listeriosis have been well described, recent investigations of point-source foodborne outbreaks of listeriosis have further confirmed the clinical entity of a milder, noninvasive gastrointestinal illness characterized by fever, nausea, vomiting, diarrhea, headache, and musculoskeletal symptoms, indistinguishable from other common presentations of food poisoning.[5–7,14,15] Such an illness may be a prodrome of a more severe, invasive infection, especially in groups known to be at high risk for invasive disease. Table 1 contains a categorization of *L. monocytogenes* infections.

In pregnant women (perinatal listeriosis), infection may present as a flu-like illness with fever, headache, and myalgia and progress to amnionitis and premature labor.[16] The corresponding intrauterine infection is usually apparent at birth or within the first few days of life. This congenital infection, granulomatosis infantisepticum, is characterized by a severe, often fatal, disseminated, multiorgan infection. In contrast, newborns who acquire listeriosis at the time of delivery or shortly thereafter are usually full term and the product of an uncomplicated pregnancy. These infants acquire *L. monocytogenes* at delivery when exposed to a contaminated birth canal or via nosocomial transmission in the hospital.[17–21] In this group, the clinical presentation is more likely to be meningitis than overwhelming sepsis.[20,21]

Sporadic cases are the rule, but outbreaks have been well described due to an expanding variety of contaminated foods including cole slaw, corn, cheese, butter, milk, smoked fish, and other seafood products and processed meats.[1,3,22,23] The number of outbreaks recorded has been small and predominantly in North America and Europe. However, given the nature of the organism, there is no reason

Table 1. ***Listeria monocytogenes*** **Infection**

Host	Illness	Type of infection
Gravid woman	"Flu-like" syndrome	Bacteremia and/or chorioamnionitis
Neonate	Disseminated, lethal septic disease	*In utero*, widely disseminated, multiorgan disease; "granulomatosis infantiseptica"
	Sepsis and/or meningitis	Postpartum bacteremia (may or may not progress to meningitis)
Adult (often immuno-compromised)	Sepsis and/or meningitis	Bacteremia (may or may not progress to meningitis)
	Meningoencephalitis, rhomboencephalitis, cerebritis or brain abscess	Subacute cerebritis and/or meningitis (usually does not progress to brain abscess)
Any age	Focal infection[a]	Resulting from bacteremia or direct inoculation (skin)
	Gastroenteritis	Mild gastroenteritis following recent exposure to contaminated food product, usually self-limited

[a]Includes skin, ocular, lymph node, endocarditis, arteritis, artificial valve and stent infection, pneumonia, osteomyelitis, prosthetic joint infection, spinal or brain abscess, peritonitis, cholecystitis, and hepatitis.

to believe that the disease is limited to these regions. Rather, listeriosis may be occurring but not detected due to difficulties with bacterial isolation and identification.[22] Nosocomial outbreaks have also been described in newborn nurseries and renal transplant units.[17–20] Since pregnant women appear to be highly susceptible to this infection, the occurrence of listeriosis in pregnant women should alert public health officials to the possibility of community-wide exposure to *L. monocytogenes*, as it can be assumed that many more people are exposed than develop disease.

2. Historical Background

L. monocytogenes was first isolated from necrotic lesions in the liver of rabbits in 1919, and named *Bacillus hepatitis*.[24] This was the same year that French clinicians isolated and preserved a "diphtheroid" from spinal fluid cultures of a patient with meningitis, subsequently identified as *L. monocytogenes*.[25] In 1924, this organism was named *Bacterium monocytogenes* for the monocytosis that is associated with systemic illness in an outbreak among laboratory rabbits in England.[26,27] The etiologic agent of an epizootic among wild gerbils from South Africa was identified as *Listerella hepatolytica* in honor of the father of antisepsis, Joseph Lister.[28] The organism was named *L. monocytogenes* in 1940.[29,30] Despite the name of the organism, monocytosis is an unusual feature of human infections.

Initially recognized as an infection of animals, *L. monocytogenes* was considered a veterinary disease, causing epizootics in sheep and cattle, with manifestations of abortions and basilar meningoencephalitis ("circling disease") in mammals. In humans, the association of a *Listeria* infection in pregnancy and severe disease in the fetus was first described in 1936,[31] and the association between *L. monocytogenes* and neoplastic disease was first reported by Louria and colleagues in 1967.[32] Since then, confirmatory reports have further identified a range of underlying conditions that increase the risk of listeriosis. These include renal and other organ solid transplant patients,[33] alcoholism and cirrhosis,[34] diabetes mellitus, and conditions that are typified by dysfunctional cellular immunity, including persons on immunosuppressive doses of adrenocorticosteroids,[35–40] and those with HIV infection.[12,13]Among those with malignancies, the majority suffer from hematologic malignancies that are characterized by impairment of cellular immunity, in particular Hodgkin's disease, non-Hodgkin lymphoma, and lymphatic leukemias.[39,40] Among transplant recipients, cytomegalic virus infection may also be a predisposing factor in *Listeria* superinfection.[41]

Well-characterized food outbreaks have been reported.[1–6] Clusters of cases have also occurred among immunocompromised hosts and in hospital settings where the source of nosocomial transmission was not always identified.[16–18,33,36,42–44] A well-documented investigation of an outbreak of listeriosis among newborns at a hospital in Costa Rica linked to aspiration of mineral oil used to bathe infants provided overwhelming evidence that transmission is not limited to the ingestion of contaminated foods.[19] In one study, contact with a single caregiver and inadequate handwashing were implicated.[45]

Gastrointestinal carriage of *L. monocytogenes* without signs or symptoms of systemic listeriosis has been well documented. Prevalence rates in community studies range from 1–5% to 5–29% (the latter in healthy abattoir workers and high-risk groups).[46,47] Recent studies have also documented the increased rate of asymptomatic stool carriage in up to one-fifth of the household contacts of patients with listeriosis. However, despite these carriage rates, secondary cases within a household have not been documented. This

reinforces the importance of the susceptibility of the host exposed to this organism, and constitutes additional evidence that exposure greatly exceeds observed disease.[48–53] Rates ofintestinal carriage of *L. monocytogenes* by pregnant women may reach 40%.[49] Gastric acidity protects against *L. monocytogenes* colonization; stool carriage rates increase substantially in patients treated with H_2-antagonists.[54]

3. Methodology

Since *L. monocytogenes* infections have not been reportable in most counties until recently, including the United States, accurate figures on incidence are not generally available. In an effort to improve the accuracy of surveillance data in the United States, in 1986, the Council of State and Territorial Epidemiologists (CSTE) recommended that listeriosis be made a reportable disease and highlighted the importance of clinical microbiology laboratories as an important source of case reports. Prior to this, the most comprehensive US study was based on hospital discharge data from hospitals participating in the Professional Activities Study (PAS) of the Commission on Professional and Hospital Activities (CPHA), a nonprofit, nongovernmental hospital discharge data system.[3] The data set was generated from the data bank of the CPHA-PAS-participating hospitals using the discharge diagnosis of listeriosis during 1980, 1981, and 1982. The number of hospitals participating in PAS ranged from 1354 (1980) to 1283 (1982), with a mean of 1309 hospitals per year. These hospitals represented 22–23% of all short-term, nonfederal hospitals in the United States and included 27–29% of all US discharges from such hospitals. For each state, total hospitalizations for listeriosis were projected by dividing the number of cases from participating hospitals in a given state by the proportion of all the states' discharges that were from PAS hospitals. A more accurate measure of listeriosis in the United States has been reported by CDC investigators' active surveillance project that began in 1986 and collected data from biweekly communication with infection control coordinators at all acute care hospitals in a several state area (see below).[3,55]

Following four large foodborne outbreaks of listeriosis in North America in the early 1980s, the CDC initiated an active surveillance project with six geographically distinct state and county health departments covering a total population base of approximately 34 million persons, representing over 14% of the US population.[3] In these surveillance areas (Missouri, New Jersey, Oklahoma, Tennessee, Washington, and Los Angeles County), all patients in whom *L. monocytogenes* was isolated from cultures of normally sterile body sites were reported to the state's or county's Listeriosis Study Group coordinator via biweekly telephone reports by hospital-based contacts (usually the infection control nurse) at each of the 666 acute-care hospitals. A single-page case report form with demographic and clinical information was completed for each case. The clinical isolates of *L. monocytogenes* from these case patients were confirmed and serotyping and molecular fingerprinting by multilocus enzyme electrophoresis were performed to further characterize these clinical isolates. This multi-state active surveillance system has been maintained, with some modifications, since 1986, replacing the passive reporting system based on data from hospital discharge diagnoses.[55] In 1996, the Foodborne Diseases Active Surveillance Network (FoodNet) of CDC's Emerging Infections Program began collecting data on foodborne illnesses, first in five and subsequently in ten states (California, Colorado, Connecticut, Georgia, Maryland, Minnesota, New Mexico, New York, Oregon, and Tennessee). This intensive, ongoing assessment of listeriosis in the United States over time has supplied a measure of the impact that educational efforts and the concomitant tightening of regulations of the food industry have had on the health of the public.

3.1. Sources of Mortality Data

Sources of mortality data include case reports, descriptions of outbreaks, reviews, and recent epidemiological surveillance and surveys. Mortality rates vary considerably with the age and underlying medical condition of the host. At least 20% of pregnancies complicated by listeriosis result in intrauterine fetal death, but only rarely does this infection persist in the mother following delivery. However, the full impact of listeriosis in pregnancy may be underestimated, as suggested by a French study where researchers cultured *L. monocytogenes* from the placentas and/or fetuses of 1.6% of all pregnancies that resulted in preterm labor or spontaneous abortion.[56] In the severest form of congenital infection, granulomatosis infantisepticum, mortality has ranged from 33 to 100%.[48,57,58] In contrast, late-onset neonatal cases (onset between 8 and 28 days of life) are more likely to present with meningitis than sepsis and have a more favorable outcome compared with early-onset neonatal cases.[20,21`] In the largest North American epidemic of listeriosis in Los Angeles in 1985, there was a 63% case fatality rate for early-onset neonatal cases, in contrast with a 37% case fatality rate among late-onset neonatal cases.[4]

The CDC's 1986 *Listeria* surveillance project documented that the case fatality rate in patients with sepsis (40%) was higher than that of patients with meningitis

(27%), although the difference was not statistically different and may have been affected by a misclassification bias due to a lack of cerebrospinal fluid (CSF) cultures.[3] In invasive disease, overall mortality rates have been estimated as 19–35%, with the rate increasing with increasing age.[22,55,59]

3.2. Sources of Morbidity Data

Since reported listeriosis cases are usually due to severe invasive disease, patients are usually hospitalized. Therefore, sources of morbidity data are similar to those of mortality data. Among 27 states participating in the National Bacterial Meningitis Surveillance Study, there were 265 cases of *Listeria* meningitis between 1978 and 1981.[60] In some regions, *Listeria* was reported as the second most common cause of neonatal meningitis (after Group B streptococcus) and the second most common cause of meningitis in individuals over 60 years old (after *Streptococcus pneumoniae*). Sources of morbidity data have also been obtained from epidemiological surveillance and from investigations of outbreaks of listeriosis.[57,58,61–66] The recent documentation of a mild, self-limited gastrointestinal syndrome associated with the ingestion of *Listeria*-contaminated food products highlights the fact that additional cases of *Listeria* infection in the community almost certainly go undetected.[5–7,14,15]

3.3. Surveys

The detection and investigation of recent epidemics underscore the need for improved surveillance of listeriosis. Even though the attack rate of epidemic listeriosis may be four- to six-fold higher than the background rate,[67] since the absolute attack rate during an epidemic may be as low as 0.8–2.0 per 10^5 population, an ongoing epidemic may not be observed in a community, especially if patients are being diagnosed and treated at several hospitals in the community. In the epidemic in Los Angeles County in 1985 associated with a contaminated Mexican-type soft cheese, the outbreak was detected by an alert infection control nurse in the county women's hospital that provided care for the largest segment of the Hispanic population. It was only after an unusual number of cases occurred in this hospital that Los Angeles County health officials were notified and the full extent of the community-wide outbreak was revealed.[4] Had the 142 cases in Los Angeles County been distributed throughout the hospitals in the county, it is unlikely that the few patients at each hospital would have been other than a clinical curiosity.

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. Isolation and identification of the organism are not difficult as long as laboratory personnel recognize the importance of scrutinizing gram-positive, diphtheroid-like organisms for the possibility of being *L. monocytogenes*.[32,68] *L. monocytogenes* is motile and hemolytic, unlike other "diphtheroids." The organism's tumbling motility is best seen at room temperature and characteristic hemolysis may be minimal but enhanced with passage. Presumptive identification can be made based on these properties, while final identification requires an additional 24 hours.

In cases of meningitis, the organism is seen on Gram stain in only 10% of cases. The absence of organisms on Gram stain in the presence of a pleocytosis in the appropriate host should strongly raise the possibility of *L. monocytogenes*. When attempting to isolate the organism from food, stool, or environmental sources, holding specimens at 4°C has resulted in improved yields, but this "cold enrichment" technique has not been demonstrated to be more efficacious with clinical specimens such as CSF, blood, or others.[68] The cold enrichment method has been improved upon by the United States Department of Agriculture's (USDA) culture method.[69,70] Because of concern of *Listeria* contamination in the food industry, a variety of rapid diagnostic techniques have been developed for its detection in food and environmental samples. These have included spectroscopy,[71] genetic probes based on the listeriolysin O gene sequences or species-specific rRNA sequences,[72,73] other genetic probes,[74] monoclinal antibodies to cell surface antigens,[75] and a variety of polymerase chain (PCR)-based methods.[74,76,77,78] In the future, additional rapid identification tests will be available, based primarily on PCR methodology, but also probably using nanotechnology.

Of the seven species of *Listeria, L. monocytogenes* is considered to be the principal human pathogen, although there are case reports of invasive listeriosis caused by species other than *L. monocytogenes*, including *L. innocua*[34,79–81] There are 11 serotypes of *L. monocytogenes*, differentiated on the basis of agglutination of somatic (O) and flagellar (H) antigens.[52,68] Serotypes 1/2a, 1/2b, and 4b account for over 90% of all isolates, although the distribution of these serotypes may vary by geographic region.[3,55,63,68] Other than the fact that the majority of *Listeria* infections are caused by these three serotypes, no clinical differences in disease presentation or severity have been demonstrated among the various serotypes.

Since just three principal serotypes cause most human disease, serotyping systems have been of limited use in epidemiological investigations, including

outbreaks and attempts to link sporadic cases of listeriosis to an implicated food item or environmental specimen. More discriminatory subtyping techniques include phage typing [63,62] pulse-gel electrophoresis,[83–88] multilocus enzyme electrophoresis,[89–92] restriction fragment length polymorphism (RFLP),[93–95] multi-virulence locus sequence typing,[96] ribosomal DNA fingerprinting (ribotyping),[85,87,97–99] and PCR-based randomly amplified polymorphic DNA patterns (RAPD) or repetitive element sequence analysis,[98,100–102] and mixed genomic microarrays.[103] These increasingly sophisticated techniques are powerful tools in epidemiologic assessment of both outbreaks and sporadic cases.

3.4.2. Serological and Immunological Diagnostic Methods. *L. monocytogenes* has several antigens that cross-react with other gram-positive organisms; therefore, false-positive serological results may occur. Further, gastrointestinal carriage studies and the recently described mild gastrointestinal manifestations of *L. monocytogenes* infection suggest that exposure may be widespread.[5–7,14,15] Therefore, *Listeria* agglutination titers may be detected in persons without evidence of having experienced invasive listeriosis. Forexample, 40% of abattoir-associated personnel in India (in the absence of clinical disease) were found to have anti-*Listeria* antibodies (Igm and IgG) using a dot-ELISA technique.[46] Earlier attempts at serological diagnosis were limited by the lack of sensitivity and specificity of the available assays, and false-negative serological tests were observed in patients with culture-proven listeriosis, especially in newborns and immunosuppressed patients,[1,68,80,104,105] however, the use of an improved antilisteriolysin O assay as part of a preliminary outbreak investigation shows promise.[106] Like many serological tests, this one offers little assistance in the clinical management of a patient.

4. Biological Characteristics of the Organism

Its precise ecological niche is unknown, but *L. monocytogenes* has been isolated from a wide variety of environmental sources. Its survival in the environment was best documented from quantitative bacterial counts demonstrating persistence of viable organisms for at least 2 months in various agricultural settings.[107] Carriage studies have repeatedly demonstrated that the organism can survive in the human gastrointestinal tract.[48–53] In addition, it has been shown to live in the gastrointestinal and genital tract of a variety of animals ranging from shellfish to birds and most mammals. Its predilection for immunocompromised hosts, including pregnant women, attests to its low pathogenicity in immunologically normal individuals.

5. Descriptive Epidemiology

Initially described as a zoonosis, *L. monocytogenes* is responsible for abortion, mastitis, septicemia, meningitis, and encephalitis in cattle and sheep and is the etiologic agent of circling disease. Zoonotics in sheep and cattle have been attributed to poor-quality silage, a link that has been speculative and only rarely documented.[108,109]

Investigation of a series of outbreaks of human listeriosis since the early 1980s has clearly demonstrated that listeriosis is a foodborne disease. Although the bulk of human listeriosis occurs as individual "sporadic" cases rather than in the setting of an outbreak, investigations of such cases have continued to demonstrate that they often result from an encounter between a susceptible person and a *Listeria*-contaminated food item. The lessons learned from the investigation of epidemics regarding foods at high risk of *Listeria* contamination coupled with increased concern of food safety at a microbiological level is likely responsible for the marked decline in human listeriosis in the United States over the past decades.[55] After initially concentrating on dairy products, both FDA and USDA's Food Safety Inspection Service (FSIS) have broadened their surveillance for *Listeria*-contaminated products following a well-documented outbreak of listeriosis that was linked to a contaminated turkey frankfurter.[110–114] Following the epidemics in the early 1980s, these agencies ultimately developed a "zero tolerance" posture. In 1986, the first full year of the program, over 40 commercial food products were recalled or kept from being distributed due to *L. monocytogenes* contamination.[3] Since then, over 30 food recalls have been initiated each year, including ready-to-eat delicatessen meats and poultry products, prepared salads, and seafoods.[55,115]

5.1. Prevalence and Incidence

5.1.1. Asymptomatic Carriage. Epidemiological evidence that listeriosis is usually a foodborne infection is further strengthened by studies of asymptomatic gastrointestinal carriage. This has been well documented, although prevalence rates have varied in different studies as a function of the subject selection, sampling frame, and culture technique. However, since the identification of *L. monocytogenes* from cultures of samples contaminated with other bacteria can be difficult and since many of these carriage studies were conducted prior to the development of selective and sensitive

culture techniques, it cannot be certain that these rates reflect only pathological strains of *Listeria*. Nevertheless, these rates have ranged from 1–5% in community-based studies to 5–29% in healthy abattoir workers and poultry workers to 8–26% among household members of listeriosis patients, the latter presumably having similar exposure risks as the case patient, further evidence that exposure may greatly exceed observed disease.[48,51,52,115]. Indeed, an intensive 1-year study of 3 healthy volunteers (242–363 stool specimens) showed an overall 1.15% *L. monocytogenes* isolation rate, but evidence of 5–9 exposures to *L. monocytogenes* per person per year in the absence of clinical disease.[116]

5.1.2. Gastroenteritis. The isolation of *L. monocytogenes* from stool may be problematic. Population-based studies of listeriosis have focused on invasive disease with a case definition that depends on the recovery of *L. monocytogenes* from a normally sterile site. Therefore, the full burden of *L. monocytogenes* morbidity is also likely to have been underestimated. Mild gastrointestinal illness attributed to listeriosis has been frequently documented,[6,7,14,15] but it is difficult to distinguish from a variety of pathogens and conditions that are characterized by similar symptoms.

5.1.3. Invasive Infection. Despite the indirect evidence from food microbiology and gastrointestinal carriage studies that exposure to pathogenic *L. monocytogenes* is common, serious infection is *infrequent*. Infection occurs primarily among pregnant women and their neonates, hosts immunocompromised by their underlying illnesses or medications, and the elderly.[22,117] Prior to the CDC's active surveillance studies and the CSTE's recommendation for laboratory reporting of cases of listeriosis in 1986, estimates of the incidence of listeriosis depended on passive reporting systems or hospital discharge data. These methods were acknowledged to underestimate the true burden of disease and made it difficult for direct comparisons of incidence data collected in different ways.[53] The CDC's study of hospital discharge data between 1980 and 1982 estimated the annual incidence of listeriosis in the United States to be $0.36/10^5$, accounting for approximately 800 cases and over 150 deaths (case fatality rate, 19%). In contrast, in the CDC's more intensive 1986 active surveillance study incidence rates were nearly twice that estimated by hospital discharge data.[3] In Europe in 1986–1987, incidence rates ranged from $0.5/10^5$ in the United Kingdom to $1.1/10^5$ in France.[118,119] Whether these differences reflect true difference in incidence or differences in surveillance and reporting have not been assessed.

The CDC's active surveillance project identified 246 cases of listeriosis that occurred among residents of the surveillance areas in 1986; the overall incidence was $0.7/10^5$: 67 perinatal cases ($12.7/10^5$ live births) and 179 cases in nonpregnant adults (non-perinatal cases, incidence = $0.5/10^5$). From these data, it was estimated that in 1986 at least 1700 cases of listeriosis occurred in the United States annually, resulting in approximately 450 deaths. The incidence of listeriosis increases with advancing age; more than 80% of non-neonatal patients with listeriosis are over 50 years of age and over 40% are 70 years of age or more[3]. This age distributionappears to reflect both heightened risk due to immunologic deficits that accompany the aging process and the greater prevalence of underlying diseases that predispose to *Listeria*, as well as the use of *Listeria*-promoting medications to treat these underlying conditions.

In pregnancies complicated by *L. monocytogenes* infections that resulted in intrauterine fetal death, gestational age was not uniformly reported; however, the earliest documented gestational age reported was 11 weeks. Perinatal incidence was four times higher in Los Angeles ($24.3/10^5$) than in other areas ($5.2/10^5$ births, $p = 5 \times 10^{-5}$), and race-specific perinatal rates in Los Angeles were higher among blacks ($51.1/10^5$ births than among whites ($21.7/10^5$ births) or Hispanics ($22/10^5$ births), $p = 0.03$. The perinatal rate for whites and blacks in Los Angeles was higher than comparable race-specific rates in the other areas (whites = $10.7/10^5$ births, blacks $5.6/10^5$ live births, $p = 0.003$). The higher rates could not be attributed to maternal age or serotype distribution. Since this 1986 surveillance study occurred during the year following the well-publicized cheese-borne listeriosis epidemic in Los Angeles, it was speculated that clinicians may have had a heightened index of suspicion and increased the number of cultures they performed to rule out a *Listeria* infection.

In the CDC's 1986 surveillance project, 162 clinical isolates were serotyped. Three serotypes (1/2a, 1/2b, and 4b) accounted for nearly 95% of all strains: 30% were serotype 1/2a, 32% serotype 1/2b, and 33% were serotype 4b. The remaining nine strains were distributed among three additional serotypes: 3a, 3b, and 1/2c. These isolates were further subtyped by multilocus enzyme electrophoresis and found to be distributed among 37 distinct electrophoretic types, a method by which all strains can be typed.[89] This demonstrated both the diversity of the species and the promise of molecular biological techniques to clarify the epidemiology of listeriosis.[3]

Between 1996 and 2006, the CDC FoodNet surveillance population increased from 14.2 million persons (5% of the US population) in five states to 44.9 million persons (15% of the US population) in ten states. During that period, compared to the 1996–1998 baseline, the incidence of laboratory-confirmed *Listeria* cases has decreased by 34% to 0.31 per 100,000.[120] It is likely that multifaceted prevention efforts by industry, food regulatory agencies, and from widely disseminated consumer guidelines have been responsible for

this decline (Figure 2). In France between 1987 and 1997, an incidence reduction of 68% was observed, again attributed in large part to prevention efforts.[121]

Case fatality rates have varied considerably depending on age and extent of underlying disease of the populations studied. At one cancer center between 1955 and 1997, it was 39%.[37] Mead and colleagues calculated a 20% case fatality rate for invasive listeriosis based on 1997 US data.[122] Siegman-Igra and colleagues reviewed infectious disease reports of non-perinatal *Listeria*, a total of 1,149 cases published in the 1990s; case fatality rates ranged from 24 to 52%, averaging 36%. In six reports of perinatal listeriosis with a total of 494 cases combined intrauterine and postnatal case fatality rates ranged from 19 to 45%, averaging 33%.[123] In another review (of 222 cases), the perinatal case fatality rate was about 20%.[124]

Examination of CDC incidence and crude mortality data in the 2003–2006 time period suggests current case fatality rates area considerably lower than the 20%[120,125] reported by Mead and colleagues for 1997, almost all of whom were hospitalized. Lower current case fatality rates could be related to inclusion of more isolates from febrile gastroenteritis cases, more effective treatment, or better control of underlying diseases with resultant more robust host anti-*Listeria* immune mechanisms.

5.2. Epidemic Behavior and Contagiousness

Neonatal infections aside, the majority of listeriosis epidemics have implicated contaminated food items. Foods have included milk,[2,5] butter,[126] soft cheese,[4,127] cole slaw,[1]smoked fish, other seafood products,[84,128] ready to eat deli meats, frankfurters, and poultry products.[88,111,129,130] In 2002, a nine-state outbreak of listeriosis due to an unusual strain implicated turkey deli meat and was traced to two production facilities.[88] Contamination of dairy products may have occurred either from contaminated milk obtained from cows with *Listeria* mastitis or as a result of in-process or post-pasteurization contamination of products being prepared and packaged in *Listeria*-contaminated environments. Similarly, *Listeria* can contaminate meats and seafoods at anystage of the food production process. The cole slaw contamination was attributed to the local practice of fertilizing with sheep manure. Unfortunately, in this circumstance the source of manure was from a sheep herd that had apparently suffered a *Listeria* epizootic. Since the cabbage was kept in silos over the winter, enhancement of bacterial growth by an unintentional cold enrichment process was also considered as a contributory factor.

It is apparent that, in several of the community-wide outbreaks linked to contaminated food items, many more are exposed than become ill.[131] Carriage studies have shown elevated rates of asymptomatic carriage in household contacts of listeriosis patients, as well as members of the community at large, even among individuals considered to be at high risk of acquiring listeriosis.[37,49–52] Other than vertical transmission from a pregnant woman to her fetus, no cases have been linked to person-to-person transmission although outbreaks among neonates in hospital settings have raised suspicion about cross-contamination.[19,132–134] The descriptions of a milder, noninvasive form of listeriosis characterized predominantly by gastrointestinal symptoms have demonstrated a broader spectrum of illness; however, there is no evidence that differences in clinical presentation are linked to strain-specific differences among *L. monocytogenes* isolates. In contrast, although there are case reports of *Listeria* species other than *L. monocytogenes* causing disease, all strains of *L. monocytogenes* are considered to be potential pathogens. The reason why just 3 of the 11 serotypes are responsible for the bulk of disease remains unanswered.[3]

The infectious dose of *L. monocytogenes* in humans is not known, although it is likely that there is an interaction between the host susceptibility and the size of the inoculum. This is supported by feeding studies of steroid-treated mice, Sprague–Dawley rats with altered gastric acidity,[135,136] and feeding trials in nonhuman primates.[137,138] Nevertheless, since the bacterial counts of *Listeria*-contaminated food items may increase with prolonged shelf life and since differences in host defense mechanisms influence susceptibility to *L. monocytogenes*, a zero tolerance standard has been adopted by the food industry.[139] It has been proposed that infection may occur either after ingestion of a single large dose of *L. monocytogenes* or after repeated ingestions of smaller doses.[116]

5.3. Geographic Distribution

Surveillance studies, outbreak investigations, and case reports of listeriosis, coupled with its ubiquity in the environment, suggest that *L. monocytogenes* has a worldwide distribution. Differences in disease rates have been attributed to differences in surveillance and/or the likelihood of exposure to foods that may be contaminated.

5.4. Temporal Distribution

The incidence of listeriosis is generally believed to be higher in humans from the late spring to early fall.[3] In other

animals it appears more often in the winter. Presumably this is related to seasonal exposure to contaminated food or environmental sources, but this has not been adequately documented.

5.5. Age

The very young and very old have the highest incidence rates and mortality rates. Beyond the neonatal period, the incidence of listeriosis remains low until the *seventh* decade of life, when it increases with advancing age. More than 40% of cases occur in individuals 70 years of age or more.[3,55] In the immunosuppressed patient the age varies with the reason for immunosuppression and the age of onset of the underlying immunosuppressing condition (e.g., pregnancy, organ transplantation, and HIV infection).

5.6. Sex

Other than the predilection for pregnant women, there are no significant gender-specific differences in incidence, clinical presentation, or severity of disease.

5.7. Race

Differential rates of disease may be associated with food items to which some groups may be more likely to be exposed; however, there are no data to support differences in disease that are inherent to specific racial or ethnic groups.

5.8. Occupation

Other than a handful of case reports of cutaneous listeriosis among veterinarians, farmers, and ranchers, most of whom participated in the delivery of infected and aborted calves, there are no defined occupational risks for developing invasive listeriosis.[140,141] Groups with greater exposure to the organism may have higher gastrointestinal carriage rates, however, but there is no evidence that disease is more common.

5.9. Occurrence in Different Settings

In addition to community-wide foodborne epidemics, small outbreaks in organ transplant units and newborn nurseries have been described.[33,45,132–134,142]

5.10. Socioeconomic Factors

There are no known socioeconomic factors that affect risk of acquiring listeriosis.

5.11. Other Factors

Several reports have suggested that underlying gastrointestinal conditions such as reduced gastric acidity,[42,59,136] a concomitant gastrointestinal infection,[143,144] or a recent gastrointestinal procedure[145,146] may facilitate invasion and result in a systemic infection. Whether these represent true risk factors is a hypothesis that has yet to be adequately addressed.

6. Mechanisms and Routes of Transmission

The growing number of reports of sporadic listeriosis traced to a contaminated food product and the evidence of contaminated foods as the source of community-wide outbreaks have confirmed that listeriosis is a principally foodborne infection, although the well-documented epidemic of nosocomial listeriosis traced to contaminated mineral oil aspirated by newborn infants in the nursery demonstrates the epidemic potential in other settings.[19] However, given the ecology of this organism, it is likely that contaminated food products are ultimately linked to an infected animal, with the subsequent direct or indirect contamination of selected food products during preparation, processing, or packaging. The gastrointestinal reservoir offers the potential for person-to-person transmission via fecal–oral spread, but there is no evidence to support this hypothesis. As noted earlier, direct contact with this bacterium has resulted in focal infections in those attending the delivery of infected or aborted calves.[140,141]

7. Pathogenesis and Immunity

The investigation of outbreaks and well-documented point-sources of exposure to *Listeria*-contaminated foods has helped to clarify the incubation period of foodborne listeriosis and may range from as short as 2–3 days to 2–4 weeks.[4,15,129] In addition, there are also reports that suggest that it may be considerably longer, although documentation of a precise point of exposure limits generalizations of reports of protracted incubation periods.[4] Also, persons with known risk factors for listeriosis may be transient asymptomatic carriers and never develop invasive disease.[116,147]

Once it invades, the organism appears to reside in the protected environment of nonactivated macrophages where it is shielded from antibiotics, a feature that has important implications for antimicrobial therapy. An in vitro human enterocyte-like model suggests that *L. monocytogenes* is protected by intracellular vacuoles resulting from phagocytosis and that listerolysin O, a hemolysin with structural and physiological similarities to hemolysins of *S. pneumoniae* and *S. pyogenes*, constitutes one virulence factor whereby the intravacuolar bacteria can escape into the cytoplasm proper, an environment conducive to replication.[148–151] Only *L. monocytogenes* and *L. ivanovii*, but not other species of *Listeria*, produce this toxin.[149] In the 1960s, the importance of the mononuclear phagocyte in host resistance to *L. monocytogenes* was demonstrated.[152,153]

Both innate and acquired immunity appear critical in controlling invasive *Listeria* infections.[23,154–157] The former is important in the early stages; neutrophils, natural killer cells (secreting interferon gamma), and macrophages all appear to play a significant role. Subsequently acquired immunity develops, mediated primarily by CD8 T cells both by cytotoxic activity and by secretion of multiple cytokines, including interferon gamma (INF gamma) and tumor necrosis factor alpha (TNF alpha). The importance of TNF alpha in controlling *Listeria* infections provides a compelling explanation for the supervention of severe invasive *Listeria* infections in patients given TNF alpha blockers for the treatment of rheumatoid arthritis, Crohn's disease, or psoriasis.(8–11)

Antibody, complement, and CD4 T lymphocytes were, in the past, thought to play virtually no role in defense against *Listeria*. Recent evidence suggests that they do play a lesser role, though the importance of that role remains unsettled.[154–158]

In recent years, a great deal of research has elucidated the complexity of the host–*Listeria* relationship, the role of multiple *Listeria* components that aid its invasive and growth capacities, and the T-cell-dominated host defenses. The many elegant studies also make it clear that there is still a great deal to learn about the host–*Listeria* relationships.[23,154–157]

8. Patterns of Host Response

8.1. Patterns of Host Response

The response observed in histopathologic studies of both animal models and human disease varies from the production of a neutrophilic exudate to granulomas. This is reflected in the CSF pleocytosis, which varies from a predominantly neutrophilic to a predominantly mononuclear response. The investigation of foodborne epidemics and recent documentation of a mild form of listeriosis with predominantly gastrointestinal manifestations suggests that the gastrointestinal tract is the initial portal of entry; however, no gastrointestinal lesion has been consistently observed. Investigators of an epidemic in Philadelphia caused by several different strains of *L. monocytogenes* hypothesized that a predisposing gastrointestinal infection with another pathogen may have impaired the gastrointestinal barrier, increasing susceptibility to *Listeria* invasion.[143,144]

8.1.1. Non-perinatal Listeriosis. In immunocompromised and older adults, the clinical presentation is usually one of sepsis or meningitis, meningoencephalitis, cerebritis, or a brain abscess. The noninvasive gastrointestinal illness characterized by fever, nausea, vomiting, diarrhea, and musculoskeletal symptoms has not consistently been observed as a prodrome of an invasive infection. Focal infections, the result of or a concomitant of bacteremia, may occur at virtually any site, most commonly affecting the central nervous system. *Listeria* infection can present as cerebritis, rhombencephalitis, single, or even multiple brain abscesses.[159–162] As with *Listeria* sepsis and meningitis, these usually occur in people with complex multifaceted immune defects. In recent years, many reports of unusual localization of *Listeria* have appeared, sites including the endocardium,[163] peritoneum,[164–166] joints (usually prosthetic joints),[167–168] vascular aneurysms or grafts,[169,170] bones,[171] lymph nodes,[172] lungs, and pleura.[173–175] Respiratory failure secondary to rhombencephalitis has also been described, as has eye involvement.[176–177]

Relative to other opportunistic infections, there have been relatively few cases of listeriosis reported in patients with AIDS[12,13] This is particularly ironic since the importance of T-cell immunity and cell-mediated resistance to infection was first demonstrated experimentally with *L. monocytogenes* in the early 1960s.[152,153] That this infection is not more common in HIV infection may reflect that nonactivated macrophages, monocytes, and neutrophils may all play an important role in immune protection against *Listeria*.[154,156–158,178,179]

8.1.2. Perinatal Listeriosis. Case reports and case series have demonstrated that *L. monocytogenes* infections tend to complicate later stage pregnancies, but perinatal infection can occur as early as the first trimester.[3,123,180] Perinatal cases of listeriosis may be underdiagnosed, especially when a pregnancy ends in a fetal death. A French study cultured *L. monocytogenes* from the placentas and/or fetuses of 1.6% of all pregnancies that resulted in preterm labor or spontaneous abortion.[56] Listeriosis should be suspected in a pregnant woman with chills and fever with no obvious source, especially if the fever is accompanied by signs of a

threatened abortion. A newborn or neonate with evidence of sepsis with or without meningitis should be suspected of *Listeria* infection.

8.2. Diagnosis

Clinicians should suspect listeriosis when confronted with unexplained fever in pregnant women and immunocompromised and elderly hosts. Blood and spinal cultures, when appropriate, should routinely be obtained. Given the difficulty of isolation of *Listeria* from clinical specimens from nonsterile sites and substantial rates of asymptomatic gastrointestinal carriage, stool cultures are not sufficiently sensitive or specific to be a helpful diagnostic aid. Though not of assistance in clinical settings, improved serological tests of antilisteriolysin O may prove useful in clarifying the epidemiology of this infection. In some cases, peripheral blood monocytosis can be a clue. In cases ofmeningitis polymorphonuclear or mononuclear cell counts can range from a few toseveral thousand; in rare cases, cerebrospinal fluid cultures are positive in the absence of pleocytosis.[181] Cerebrospinal glucose concentrations range from normal to very low.

8.3. Differential Diagnosis

The differential diagnosis in a patient with meningitis includes *S. pneumoniae, Neisseria meningitidis*, or *Haemophilus influenzae*. In patients with cell-mediated immune defects, *Cryptococcus neoformans* should be included in the differential diagnosis. The absence of organisms on Gram stain may suggest tuberculosis or a partially treated bacterial meningitis as well as *Listeria* meningitis; therefore, a patient with meningitis and a CSF pleocytosis without organisms seen on Gram stain should be suspected of *Listeria* meningitis. Similarly, a clinical presentation of cerebritis with a normal CSF should also raise suspicion of *Listeria* cerebritis. In the former, the organism can be expected to be isolated from the CSF, even though not seen. In the latter, the bacteria should be isolated from blood, but may not be recovered from the CSF. The picture of clinical sepsis without meningitis or other localizing features in a patient with cell-mediated immune defects may be produced by a number of organisms, including *Salmonella* species, mycobacteria species, *C. neoformans, Histoplasma capsulatum, Coccidioides immitis*, or cytomegalovirus. *Listeria* cerebritis appears to be rather unique in that symptoms and bacteremia may occur over a longer period of time before forming a brain abscess compared with other organisms, a manifestation that has been confused with *Toxoplasma gondii* encephalitis. In the pregnant woman, the illness resembles influenza or a urinary tract infection. In the neonate, the usual causes of neonatal sepsis and meningitis such as *Escherichia coli, Klebsiella pneumoniae*, group B streptococci, the enterococci, and *Bacillus* species must be considered. There is nothing specific about *Listeria* febrile gastroenteritis, thoughconcomitant abnormalities in liver function tests may suggest the diagnosis. In compromised hosts, dual infection with *Listeria* and other microorganisms such as *C. neoformans* or *Legionella pneumophila* may occur.

9. Control and Prevention

9.1. General Concepts

Although two outbreaks have implicated pasteurized milk,[2] there is ample evidence that routine pasteurization procedures easily eliminates *Listeria*.[182,183] This stresses the importance of reducing opportunities for post-pasteurization contamination. Immunocompromised hosts, such as those with cell-mediated immune defects, and pregnant women should be educated as to the dangers of improperly processed dairy products (particularly soft cheeses), poorly washed raw vegetables, and inadequately cooked meat products. The CDC specifically recommends the following:

- Avoid foods from deli counters or thoroughly heat deli meat products before eating.
- Heat hot dogs until steaming before eating.
- Avoid cross-contaminating other foods, utensils, and food preparation surfaces with fluids from hot dog packages and wash hands after handling hot dogs.
- Thoroughly cook raw food from animal sources, such as beef, pork, or poultry.
- Keep uncooked meats separate from vegetables and from cooked foods.
- Avoid raw (unpasteurized) milk or foods made from raw milk.
- Wash hands, knives, and cutting boards after handling uncooked foods.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis and Treatment

As person-to-person transmission is not a feature of listeriosis, isolation of patients with listeriosis is not warranted. Data on treatment for enteric listeriosis or to guide postexposure prophylaxis, especially in pregnant women, are lacking. In high-risk patients with a known exposure,

such prophylaxis is not generally recommended. Given its spectrum of activity and its ability to cross the blood–brain barrier, the antibiotic of choice has been ampicillin with or without gentamicin[159] (Table 2). Trimethoprim—sulfamethoxazole, generically called cotrimoxazole, has also been used successfully;[184] however, there are too few cases to permit a definitive judgment about its effectiveness. Comparative clinical trials have not been conducted to assess the most efficacious treatment for listeriosis.[185,186] Penicillin has been used, often with success, but concerns about relative penicillin resistance make ampicillin the beta lactam of choice; this is especially true in CNS *Listeria* infections. Although the value of adding an aminoglycoside, in particular gentamicin, has not been established by randomized prospective studies, in vitro synergism, and limited clinical data suggest the combination is indicated in severe or life threatening disease.[159] The efficacy of macrolides, vancomycin, tetracyclines, newer fluoroqinolones, carbapenems, and linezolid are uncertain, though in vitro data are encouraging for the last three.[40,159] Cephalosporins should not be used.[159]

9.3. Immunization

Because of the potential economic consequences of listeriosis outbreaks in farm animals, a variety of *Listeria* vaccines have been developed for agricultural use, but none is routinely used. No vaccine has been developed for use in humans.

10. Unresolved Problems

The CDC's active surveillance system has highlighted the importance of community-based surveillance and prompt reporting of cases. The recent descriptions of a mild form of listeriosis raise the question as to the degree to which *L. monocytogenes* is responsible for self-limited community-

Table 2. Differential Diagnosis and Treatment of *Listeria monocytogenes* Infection

		Treatment	
Category	Differential diagnosis	First choice	Second choice
Pregnancy infections	Influenza	Ampicillin	TMP-SMX, penicillin[a] (large doses), erythromycin, ? vancomycin
	Pyelonephritis Chorioamnionitis Septic abortion		
Granulomatosis infantiseptica	Neonatal sepsis	Ampicillin with or without gentamicin	TMP-SMX, penicillin[a] (large doses), erythromycin, ? vancomycin
	Neonatal meningitis due to enteric bacilli, group B streptococcus		
Sepsis	Sepsis of unknown source	Ampicillin with or without gentamicin	TMP-SMX, penicillin[a] (large doses) with or without gentamicin, ? erythromycin, vancomycin
Meningo-encephalitis	Viral encephalitis, metabolic encephalopathy or psychiatric illness	Ampicillin with or without gentamicin, possibly with gentamicin intrathecally	TMP-SMX, ? penicillin[a] (large doses) ? erythromycin and/or chloramphenicol, ? vancomycin
	Infection due to *Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis, Cryptococcus neoformans*, or *Mycobacterium tuberculosis* in immunosuppressed patients or group B streptococci or enteric bacilli in neonates		
Cerebritis	Brain abscess, tumor, stroke	Ampicillin with or without gentamicin	TMP-SMX, erythromycin, ? vancomycin, ? penicillin[a] (large doses)
Focal infections	Varies with site	Ampicillin with or without gentamicin	TMP-SMX, penicillin[a] (large doses) erythromycin and/or tetracycline, ? vancomycin
Gastroenteritis	Bacterial gastroenteritis		None unless evidence of sepsis

[a]The potential for increasing penicillin resistance is an issue

acquired gastrointestinal illness. These cases could serve as sentinels for an undetected common-source food item or an outbreak.

A further investigation into the virulence factors that separate pathogenic and nonpathogenic strains of *Listeria* and more specific host factors that determine susceptibility may help to better target preventive strategies for minimizing exposure to these pathogens and further reducing the substantial morbidity and mortality that these ubiquitous organisms have on the health of the public.

CHAPTER 23

Lyme Disease

Roger P. Clark and Linden T. Hu

1. Historical Perspective

In the short period of time since Lyme disease was first described in the mid-1970 s, it has rapidly become recognized as the most common vector-borne illness in the United States. In 1982, the Centers for Disease Control and Prevention (CDC) began surveillance of Lyme disease, and the CSTE (Council of State and Territorial Epidemiologists) classified Lyme disease as a notifiable disease in 1990.

As of 2003, every state in the United States except Montana had reported Lyme disease, with a trend toward increasing numbers of cases since reporting was first instituted. The majority of infections appear to be clustered in the Northeast from Maryland northward to Maine, the upper Midwest (Minnesota and Wisconsin), and northern California. In regions outside these areas, most, if not all, reported cases are imported. In 2005 more than 23,000 cases were reported in the United States with estimates of 6–12 unreported cases for every reported case.[13]

Lyme disease in the United States was first identified as a distinct entity in Lyme, Connecticut, where a cluster of 27 children and 8 adults had an illness manifesting with fever, myalgias, arthritis—and, most characteristically, a rash early in disease that was present in one-third of the patients.[98] This rash, which is characteristic of early Lyme disease, is known as erythema chronicum migrans, or simply erythema migrans (EM). Epidemiological studies implicated tick exposure and the treponeme-like spirochetal causative agent of Lyme disease was identified from an *Ixodes* tick and named *Borrelia burgdorferi*.[9]

Roger P. Clark • Infectious Diseases, Division of Geographic Medicine and Infectious Diseases, Tufts-New England Medical Center, Boston, Massachusetts, USA **Linden T. Hu** • MD, Associate Professor of Medicine, Division of Geographic Medicine and Infectious Diseases, Tufts-New England Medical Center, 750 Washington St, Boston, Massachusetts 02111, USA.

It was eventually recognized that Lyme disease in the United States had similarities to a tick-associated disease that had been recognized in Europe almost a century earlier. Afzelius described the first cases of EM lesions in European patients in 1910. Other Borrelia known to cause disease in humans have been investigated since the mid-19th century. Relapsing fever was initially proposed in 1868 to be caused by threadlike organisms by Otto Obermeier, an intern of Virchow, and acrodermatitis chronica atrophicans—a manifestation of Lyme borreliosis, was commented on by a German physician in 1883. Named successively *Spirocheta recurrentis and Spirocheta obermeieri*, these organisms finally came to be place into the genus *Borrelia* after the French scientist Borrell.[113]

2. Microbiology

Borrelia are spirochetes, belonging to family *Spirochaetaceae*.[40] Spirochetes are distinguished by a characteristic cellular structure and means of motility. *B. burgdorferi* have periplasmic flagella that are sandwiched between the outer membrane sheath and a protoplasmic cell cylinder. These periplasmic flagella, averaging from 7 to 11 in number are attached near the ends of the organism at either end and overlap at the center and account for both the shape and the motility of *B. burgdorferi*. Mutant organisms lacking the periplasmic flagella are rod-shaped bacteria and lack motility. Motility is accomplished primarily by an undulating, wavelike motion with some axial rotation, as opposed to *Leptospira* species, which achieve locomotion via a counterclockwise rotatory "corkscrew" motion.[27]

The genus *Borrelia* is composed of roughly 20 species, all of which are arthropod borne. *B. burgdorferi sensu lato* encompasses the three species that cause human disease: *B. burgdorferi sensu stricto*, *B. garinii*, and *B. afzelii*.

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_23,
© Springer Science+Business Media, LLC 2009

B. burgdorferi sensu stricto is the only species present in the United States, while all three strains are present in Europe. *B. burgdorferi* are the longest and thinnest of the Borrelia, measuring approximately 0.2–0.3μ (micrometers) by 20–30μ (micrometers).[9,31] The genome is comprised of a linear chromosome as well as a variable but abundant number of plasmids, both circular and linear. Some borrelial isolates contain over 20 of these plasmids.[25,52] Because at least several of the plasmids are considered essential for survival of the organisms, they are sometimes referred to as "mini-chromosomes."

B. burgdorferi has proven to be a very slow growing organism, with a log-phase generation time of a half a day or more.[16,75,76] It is generally cultured on one of the variants of Kelly medium such as Barbour–Stoenner–Kelly II medium (BSK II),[6] Kelly medium Preak–Mursic (MKP),[77] or BSK-H.[76] *B. burgdorferi* grows best at temperatures between 30 and 34°C in microaerophilic conditions.

In vitro culture of *B. burgdorferi* for purposes of studying the organism and its genome has been somewhat complicated by the fact that successive generations of the spirochete grown in culture will lose substantial amounts of genetic material through plasmid shedding. Plasmids will variably and unpredictably disappear, and accompanying this plasmid loss is a concomitant loss of infectivity.[35,43,45,55,83] Specific plasmids have been associated with infectivity for *B. burgdorferi* strain B31 including LP28-1 and LP25 which are required for mammalian infection and LP25 and LP28-4 which are required for tick infection.[83,105] The critical gene on LP28-1 appears to be a nicotinamidase, *pncA*.[83]

One interesting fact about *B. burgdorferi* is that the small size of the *B. burgdorferi* genome has left it with limited to no synthetic capability for many factors normally produced by other bacteria—including amino acids, fatty acids, enzyme cofactors, or nucleotides. The result is that the organism is highly dependent upon its environment to acquire these factors and has developed a tight symbiosis with its various hosts.

3. Life Cycle

B. burgdorferi are maintained in an enzootic cycle and spread to humans only incidentally. Borrelia are harbored in the midgut of hard-bodied (*Ixodes*) ticks. In the United States *Ixodes scapularis* and *I. pacificus* are the major vectors of Lyme disease, whereas in Europe and Asia *I. ricinus* and *I. persulcatus*, respectively, are the major carriers of borreliosis. In the Southern United States, a new disease called Southern Tick-Associated Rash Illness (STARI) presenting with a rash similar to EM has been associated with the bite of the *Amblyomma americanum* tick. A different borrelial species, *Borrelia lonestari*, has been identified in Southern *Amblyomma* ticks, but the linkage of this organism to STARI is now in doubt.[40,70,110,118]

Ixodes ticks feed once during each of their three life-cycle stages (larvae, nymph, and adult). Larval forms of the ticks become infected by feeding on infected animals—most notably the white footed mouse (*Peromyscus leucopus*) which is the major reservoir for *B. burgdorferi* in the United States, although birds and other small rodents also play an important role. In Asia and in Europe birds and voles are major amplifying hosts.[25] The host preference of the tick vector is an important factor in maintenance of *B. burgdorferi* in the wild. In the Southern United States where *Ixodes* ticks feed on lizards that are resistant to *B. burgdorferi* infection and whose blood is lethal for the organism, *B. burgdorferi* is not maintained in the wild rodent population. Infected larvae pass the organism transstadially during the molt to the nymphal stage and the nymphs then infect new animals when they take their blood meal. Larval ticks are most active in the late summer; nymphal ticks in spring and early summer; and adults are most active in late summer and fall. The adult ticks will often feed on larger mammals, especially the white-tailed deer. Other large animals have been found to have high borrelial titers, including sheep, dogs, and cattle.[17,52] According to the U.S. Department of Agriculture (Agricultural Research Service), cattle may be severely affected by borrelial disease, with fever, joint swelling, weight loss, and abortion. However, infection in these large mammals is not important for the maintenance of infection in the wild because they do not serve as feeding sources for larval ticks and thus are a "dead-end" host.

Once adult female ticks have mated and fed, they will drop off into the environment where they then lay their eggs, which hatch into larvae thereby beginning a new cycle. Transovarian transmission of the spirochetes is not an important factor in maintaining the organism, as only a small percentage of eggs are infected and very few of these eggs appear to remain viable.[44,66]

4. Epidemiology

The incidence of Lyme disease has been increasing steadily since it became a reportable disease in 1990. The Council of State and Territorial Epidemiologists lists the national surveillance reporting requirements for each of the states: in 42 states, reporting is required by both the provider

and the laboratory; in the remaining eight states, the task of reporting is left to the provider only. The CDC case definition of Lyme disease for surveillance purposes is "physician diagnosed erythema migrans >5 cm in diameter or at least one objective manifestation of late Lyme disease (e.g., musculoskeletal, cardiovascular, or neurologic) with laboratory confirmation of *B. burgdorferi* infection using a two-tiered assay".[59] Nationally in 2005 there were 23,305 cases of Lyme disease reported, and the incidence of Lyme disease was 7.9 cases per 100,000 population. The incidence varies widely by state, with most cases being clustered in the Eastern coastal states from Maryland to New Hampshire plus Wisconsin and Minnesota. These states account for 95% of all cases reported in 2001 and 2002.[60] There were six states (Arkansas, Colorado, Hawaii, Mississippi, Montana, and Oklahoma) reporting no cases in 2005 (Montana had never reported a case as of 2005), while New York reported 5,565 cases.[62]

A casual glance at a bar graph showing average incidence of Lyme disease from 1992 to 2003 by age group reveals a striking bimodal distribution with the two peaks at ages 5–9 years and 50–64 years, with the lowest number of cases in the 20 to 29-year-old groups. Males had a higher incidence than females in all age groups (CDC Web site). Studies from six German states where statistics on Lyme borreliosis is monitored reflect an almost identical bimodal distribution, however, there was a slight preponderance of females (55%) affected.[56]

In addition to national surveillance data, some states also keep tally of the cases independently. Connecticut lists Lyme disease cases and rates per 100,000 population by town and country. For the year 2002 the state (CT Dept. of Public Health) reported 4,631 cases with an incidence of 136 per 100,000, with one town reporting 4995.4 cases per 100,000 (692 times the national incidence). In contrast by 2005, there was a marked decrease in the number of cases and the incidence (1,810 cases and 53.1 per 100,000 respectively). This drop was due to an unspecified change in the system of reporting cases to the state, and likely not to the actual number of cases

The state of New Jersey (NJDHSS) publishes Lyme disease rate by county. In 2000, the most recent year with both number of cases and rates published, there were 2,459 cases with a statewide rate of 29.22, with a range from 2.3 to 441.02. This was markedly increased from 1999 when there were 1,719 cases (rate of 21.11) reported. In 1989 the Georgia Department of Human Resources reported 715 cases of Lyme disease. This amounted to 11 times the total number of cases reported in the combined previous 7 years (62 cases from 1982 to 1988). This may be explained by a number of factors including the fact that free serologic testing was offered during that year, and there was an extensive educational program offered to the public and physicians in 1989. It is also suspected that there was extensive over-reporting of cases in Georgia, demonstrated by the fact that in 1989, the state used a lower threshold for detection of Lyme disease (1:128 by immunofluorescence as opposed to 1:256) than other states. In 1990 new national case surveillance definitions were released, resulting in a precipitous drop in the number of cases reported in Georgia.[58] In 2005, only six cases were reported by the CDC.

In addition to the highest clustering of Lyme disease in the northeast and northern Midwestern states, a third endemic region exists in northern California and southern Oregon. The first case in California was in Sonoma County in 1978, shortly after the initial clustering of cases in Connecticut was reported. By the year 2000, there were more than 1,700 cases (cumulative) reported in California, with 95 cases reported in 2005 (Medical Board of California, CDC DVBID). Most counties in California (52 out of 58) have reported cases of Lyme disease. The nymphal ticks have been observed to have a *Borrelia burgdorferi* infection rate of approximately 40% in parts of Mendocino county, and with the rather temperate climate that California offers, ticks have been noted to be active in all seasons of the year.

Despite some of the problems in reporting and changes in case definition, it appears that there is a true increase in the total number of cases in the United States. Some of the annual fluctuations may be due to reporting changes, variation in public and physician awareness, changes in tick habitat including weather, deer and mouse populations, and many other factors. Another potential for continued widespread distribution of both tick and pathogen is via infection of birds, which can rapidly spread the disease over a large area with their migration patterns. *B. burgdorferi* has been recovered from a variety of wild birds in North America and Europe.[2,71]

In Europe the surveillance of Lyme borreliosis differs by country, and often within countries the reporting is dependent on local notification systems. In Germany for instance, there is no nationwide reporting system, But 6 of the 16 states do have a system in place for reporting of Lyme borreliosis. Within those six states the average incidence per 100,000 population was 23.3 in 2003, which was substantially increased from the previous year when the rate was 17.8 per 100,000. The majority of these cases occurred from late spring to early fall. In neighboring Austria, the estimated incidence is 300 per 100,000. In a country of eight million inhabitants, this estimate brings the total number to around 24,000 per year. Ireland, on the other hand has an estimate 0.6 cases per 100,000, despite the widespread distribution of *Ixodes ricinus* the major vector in Europe.[115]

In Sweden, a study was performed to determine the occurrence of Lyme disease in the population of southern Sweden.[7] For the year spanning May 1, 1992 through April 30, 1993, Lyme disease was made a reportable disease. During this time there were 1,471 cases identified among a population of just over 2.1 million people. There was considerable heterogeneity of incidence by region, but the overall incidence was 69 per 100,000. The clinical presentation did not markedly differ from that in the United States.

Funding for Lyme disease research grew a significant amount from 1991 to 2000 at the National Institutes of Health (NIH), while showing a very modest increase at the Centers for Disease Control and Prevention during the same period. In fact, the single year of 1998 accounts for the entire overall growth of spending at the CDC, with a decrease in allocations in all other years. The amount allocated by the NIH grew almost 100% during this period from $13.1 million to $26 million. In the same decade, the funding for research into chronic Lyme disease increased from $124,000 to $3.5 million. This reflects the large amount of money spent for health care on the entity of chronic Lyme disease.[108]

5. Pathophysiology: Host–Pathogen Interactions

The spirochete *Borrelia burgdorferi* has evolved to be capable of flourishing in physiologic conditions that can change dramatically over a very short time span. This adaptability seems in large part due to the ability to express different outer surface proteins (Osp) under various environmental conditions. The environment found in the midgut of the tick is drastically different than in the tissues of mammals or birds—in terms of temperature, pH, and host immune responses. During a tick blood meal, Borrelia in the tick midgut experience a shift in pH from 7.4 to a more acidic 6.8. There is also a rise in the temperature as blood is ingested from the warm-blooded animal into the tick which is at ambient temperature.[99] *B. burgdorferi* expression of outer surface protein A (OspA), a protein critical for tick colonization, is increased at 23°C and decreased at 32°–37°C; the expression of OspC, a protein critical for establishment of infection in mice, follows the opposite pattern. Low pH also results in decreased production of OspA.

As expected then, OspA is expressed while the organisms are in the tick midgut, but is turned off as the blood meal is being taken. The role of OspA appears to be binding to a tick midgut protein (TROSPA), allowing the organism to colonize the tick midgut.[72] As antibodies to OspA are lethal to the *B. burgdorferi*, it is advantageous to the organism that OspA production is turned off prior to encountering the mouse immune system. As OspA is being down-regulated during the blood meal, expression of OspC is increasing[21] and OspC is expressed at high levels as the spirochetes disseminate to the salivary glands,[26] in preparation for infecting a new host. Experiments in OspC-deficient Borrelia have shown that OspC is necessary to establish infection in mice, but not to disseminate and persist once the infection is established.[28] One possible explanation for this is that OspC binds selectively to a tick salivary protein (Salp15). This protein has been shown in in vitro models to provide protection against mammalian antibodies. Accordingly, in mouse models, binding of OspC to Salp15 can enhance infectivity of *B. burgdorferi*.[85]

In addition to the effects of Salp15, tick saliva provides other advantages for the spirochetes. Tick saliva contains many factors that act as immunosuppressive agents and that suppress clotting. These actions are mediated by molecules such as histamine-binding proteins (histacalins), cytokine inhibitors (such as IL-2- and IL-8-binding proteins and interferon inhibitors), leukocyte modulators, and complement inhibitors.[69] The use of tick saliva to evade host defenses is just one example of the elegant interactions between spirochete, tick, and mammal that allows the bacteria to survive in differing adverse conditions.

Other outer surface proteins are also present and involved in the mammalian inflammatory response. Included in this group of proteins are OspE, OspF, and E/F-like leader peptide. Collectively these are referred to as OspE/F-related proteins (Erps) and they may confer some degree of protection from complement-mediated killing. This family of proteins is encoded on the cp32 plasmids, and a single spirochete may produce a variety of these Erps. They appear to be encoded solely by *Borrelia burgdorferi*, as they have not been found in other Borrelia species. Both Erps and another family of proteins, complement regulator-acquiring surface proteins (CRASPs) have been shown to help the organism evade complement-mediated killing by binding host factor H. *B. burgdorferi* has at least five separate CRASPs.[92] CRASP-1 acts by binding factor H and factor H-like protein 1 (FLH-1). These are important in regulating activity in the alternative complement pathway. On binding to factor H, complement C3b is inactivated, thereby precluding complement-mediated bactericidal effects. CRASP-1 is up-regulated during the period that a tick is ingesting its blood meal, and expression of this surface protein is linked to the environmental pH.[111] Different Erps and CRASPs are expressed by different *B. burgdorferi* species and each shows differential specificity for factor H from different hosts. It has been proposed that this may, in part, explain the species predilection for different borrelial species.

While the tick is taking a blood meal, other surface proteins are being up-regulated in preparation for host invasion. Among these are the decorin-binding proteins (Dbp) A and B. These Dbps bind to decorin—a proteoglycan that is named for its ability to "decorate" collagen fibers. Also up-regulated is P66, a porin protein which is involved in binding to activated platelets via the integrin aIIbb3 (also known as glycoprotein IIbIIIa),[11] and the fibronectin binding protein BBK032.[82] A surface protein that binds to heparin sulfate and dermatan sulfate (chondroitin sulfate B) via glycosaminoglycan adhesion is called *Borrelia* glycosaminoglycan-binding protein (Bgp).[73] Each of these proteins may help the organism attach to different host tissues.

Another potential mechanism for evading host immune responses is through antigenic variation. A 34 kDa protein named variable major protein-like sequence (Vls) remains stable until a blood meal is taken by the tick. This triggers a genetic shuffling of DNA cassettes on the plasmid lp28-1. The resultant heterogeneous population of Vls variant spirochetes likely contributes to immune evasion, as suggested by the fact that loss of the Vls containing plasmid results in decreased infectivity.[43]

As organisms that disseminate in tick and mouse hosts, Borrelia require a mechanism for breaking down extracellular matrix barriers. Because *B. burgdorferi* do not produce exported proteases capable of digesting extracellular matrix proteins, it must acquire this functionality from its hosts. *B. burgdorferi* has been shown to bind plasmin and plasminogen activators such as urokinase. Binding of these proteases to *B. burgdorferi* stabilizes them and protects them from inactivation.[12,23,33,41] Binding of plasmin, which in addition to being a component of the fibrinolytic system is a broad spectrum protease, aids the organism in digesting extracellular matrix tissues and moving from the tick midgut to salivary gland and possibly in disseminating from the tick insertion site to infect distant organs. The mechanism of action of plasmin is likely enhanced by its ability to activate host matrix metalloproteinases (MMPs), which are enzymes specifically designed to digest extracellular matrix that are induced from host cells by *B. burgdorferi*. *B. burgdorferi* induces production of MMPs from multiple different tissues and the presence of active MMPs is thought to be a major factor in the development of Lyme arthritis.[32]

6. Spectrum of Disease/Clinical Manifestations

Lyme disease is an illness that can range from asymptomatic (about 10% of *B. burgdorferi sensu stricto* and probably a higher percentage of *B. afzelii* and *B. garinii* infections lack symptoms) to severe, involving many organ systems. The manifestations are typically divided into early- and late-stage symptoms. The earliest consequence of *B. burgdorferi* infection is a distinctive, transient, expanding circular or ovoid macular rash called erythema migrans (EM) that is noted at the site of the tick bite in 70–90% of cases.[94] The rash is often described as a "bull's-eye" where there is a central clearing surrounded by an expanding lesion; however, this is seen only in a minority of EM rashes. It generally evolves at the site of the bite within 5 days to 2 weeks.[67] This rash is usually non-painful, and non-pruritic, beginning as a small macular or papular lesion and expanding over a period of days to several weeks. As awareness of this condition becomes more universal in endemic areas, recollection of this erythema migrans rash has been enhanced and later studies show a much higher prevalence than initial reports indicated.

Most patients with EM rash also experience other systemic complaints concurrent with the lesions. These symptoms, which are non-specific and generally transient, include fever, headache, malaise, and myalgias. Patients may experience lymphadenopathy of nodes draining the affected site. Other early manifestations include arthralgias (distinct from true arthritis that manifests later in the course), cardiac, and neurologic findings as detailed below.[60]

6.1. Cutaneous

The localized EM rash is often followed days to weeks later by the development of multiple disseminated EM lesions. In addition, patients may develop borrelial lymphocytomas—dense lymphohistiocytic infiltrations resembling dermal lymphomas.[4] This seldom if ever found in the United States. Another clinical manifestation of Lyme borreliosis found almost exclusively in Europe is acrodermatitis chronica atrophicans (ACA), a sign of late infection involving primarily the acral regions. It is more common in the elderly and may persist for years. It is characterized by diffuse spreading inflammation of the upper dermis, leading to central skin atrophy and hyperpigmentation. These areas usually become devoid of hair and may exhibit marked irritation such as itching or hyperaesthenia. These traits may resolve to some degree with the administration of antibiotics. Borrelia have been cultured from an ACA lesion that had persisted for at least 10 years, demonstrating the ability of these organisms to thrive in the host for a remarkably long period of time.[3,5] Although the lesions tend to occur in cooler sites such as distal limbs, they have been noted to occur anywhere on the body, and not necessarily in the region of the initial EM rash.

Recently, *Borrelia burgdorferi* has been implicated as possibly being associated with mycosis fungoides, a cutaneous T-cell lymphoma. In skin biopsies taken from 83 patients with mycosis fungoides, *B. burgdorferi* was detected by PCR in 15 cases and in 0 out of 83 matched controls ($p < 0.0001$). It is hypothesized that *B. burgdorferi* may stimulate a protracted Th-1 response with accompanying build-up of CD4+ T cells, possibly leading to malignant transformation;[106] however, these studies require further confirmation.

6.2. Cardiac

Cardiac manifestations are less common than skin symptoms. The most common of the cardiac manifestations of Lyme is heart block that can vary from first degree to complete heart block, usually with a duration of under a week.[54,95] In a CDC report of 31,120 patients in 2001–2002 in the United States <1% had heart block. Studies in Europe reveal the same relative infrequency of this complication.[46] Myopericarditis occurs even less frequently, and ventricular dysfunction or failure is rare. High degree heart block may require the placement of a temporary pacemaker, but is usually transient with or without treatment with antibiotics. Cardiac complications occur during the early phase of disease and are generally not seen in late-stage Lyme disease.

6.3. Neurologic

All three species contained in the *Borrelia burgdorferi sensu lato* group have significant tropism for neurologic tissue. Of these organisms, *B. afzelii* is least likely to cause nervous system manifestations. *B. burgdorferi sensu stricto* and *B. garinii* can both present with a sometimes bewildering range of nervous system features that can prove to be confusing when no rash was initially identified.

Neurologic disorders may present with either peripheral nervous system (PNS) or central nervous system (CNS) involvement, with PNS symptoms being much more commonly reported.[29] In Europe, meningoradiculoneuritis with lymphocyte pleocytosis in the CSF (Bannwarth's syndrome) is a commonly seen neurologic phenomenon. Peripheral nerve palsies can affect many different nerves with facial nerve involvement being common. Lyme-related facial nerve palsies may at times present bilaterally—which is rare for other causes of facial palsy, but occurs in up to 10% of patients with Lyme facial palsy. Other facial nerves may be affected, including cranial nerves III–VI and VIII, which can result in balance and hearing deficits. Other forms of mononeuropathy multiplex include involvement of the brachial or sacral plexus, radiculoneuropathies (often described as "patchy and painful"), motor neuropathies,[29] and even optic neuropathy, a rare disorder found mostly in children.[86] The optic neuropathy may result in irreversible blindness even with optimal antibiotic treatment.

Other early neurologic manifestations may include disorders of cerebellar function, including ataxia, myelitis, and encephalitis. More commonly noted is Lyme meningitis which manifests as headache and neck stiffness due to the presence of the spirochetes in the CSF. Differentiating meningitis caused by this organism from other types of "aseptic" meningitis may be clinically difficult at times, as most (entero)viral meningitis occurs with a seasonality that parallels that of Lyme infection. Distinguishing features beside EM rash include the presence of cranial neuropathy and papilledema. Nearly 90% of those with Lyme as an etiology exhibit at least one of these features, compared to none of the patients with enteroviral meningitis.[19,89]

Neuroborreliosis can persist into late-stage disease causing a wide array of complications. Mild encephalopathy with decreased cognitive ability is the most common complaint. In those patients who have never received antibiotic treatment, this impairment may normalize with standard therapy. Polyneuropathies and radiculitis that developed during acute disease may persist into late-stage Lyme disease. Some of the symptoms of neuroborreliosis may linger for many years, although the majority of patients have complete resolution after weeks to months. In a Scandinavian study[7], a five-year follow-up survey of patients with documented Lyme neuroborreliosis showed that 75% of patients had a complete recovery, with 61% within the first 6 months. Those with residual problems reported difficulty with concentration, persistent facial nerve palsies, neuropathies, and/or paresthesias.

6.4. Musculoskeletal

Arthritis was the hallmark clinical finding that led to the recognition of Lyme disease in the United States. It is now known that roughly one half of those infected with *B. burgdorferi* will develop arthritis during the later stages of disease if not treated with antibiotics.[96] In Europe, there may be a lower incidence, especially in those infected by *B. afzelii*. Lyme arthritis is characterized by a relapsing and remitting form of mono or oligoarthritis that usually affects the larger joints, with the knee joint being involved most often. Of note, differentiating Lyme arthritis from other common causes of arthritis, the temporomandibular joint (TMJ) is sometimes affected.[96] Pathologic specimens of synovial tissue from patients with Lyme arthritis demonstrate mononuclear infiltration, proliferation of vasculature

as well as synovial thickening or hypertrophy. The frequency of arthritic episodes usually becomes more spaced out until eventually there is complete resolution even in the absence of antibiotic therapy. Seldom do arthritic flares occur beyond 5 years. In those patients who are treated early on in the course of Lyme disease, arthritis seldom occurs.[15] In those who are initially untreated, and develop arthritis, antibiotics will generally shorten the duration of symptoms.

A minority of patients treated with antibiotics will continue to have a more continuous, persistent arthritis that has been designated by some researchers as "antibiotic-resistant chronic Lyme arthritis." The exact mechanism of disease in these patients remains somewhat controversial, with theories centered around two core ideas: 1) an autoimmune process resulting from molecular mimicry or 2) persistence of *B. burgdorferi* (or borrelial antigens) in the joint space. *B. burgdorferi* DNA has been identified by PCR in the synovial membrane of some patients who have had extensive antibiotic therapy for Lyme arthritis.[81] Other studies have not found borrelial DNA present in large numbers of synovial fluids from patients with persistent disease. While in vitro antibiotic resistance to commonly used antibiotics has not been noted, it does not rule out the possibility of in vivo resistance of *B. burgdorferi* in association with tissues. As we will discuss in the Treatment section, there is growing evidence for persistence of *B. burgdorferi* after antibiotic therapy in both animal models and humans with Lyme disease.

There has also been some evidence to support an autoimmune mechanism for arthritis in antibiotic-resistant patients. Patients with treatment-resistant Lyme arthritis have an increased incidence of MHC class II haplotypes HLA-DRB1*0401 and 0101.[36] These haplotypes have been associated with rheumatoid arthritis and therefore serves as an attractive candidate to function as a mediator of autoimmune arthritis. Antibodies to OspA are found at greater frequency in patients with antibiotic-resistant Lyme arthritis,[37] and it has been suggested that molecular mimicry between an epitope of OspA and the human leukocyte function-associated antigen-1 (LFA-1) may be the mechanism for T-cell cross-reactivity. Subsequent data has not supported LFA-1 mimicry as a mechanism for antibiotic-resistant arthritis;[38] however, this does not rule out the possibility that a different molecular mimic exists.

The entity of "chronic Lyme disease" receives much attention in the lay press and remains a controversial topic. A multitude of unexplained illnesses, arthralgias, fatigue, and depression are all attributed to chronic Lyme disease, usually without any objective evidence. Some clinicians have even diagnosed "sero-negative" Lyme disease in patients with these non-specific symptoms and negative laboratory testing for Lyme disease. Several large studies have not shown an increase in these non-specific symptoms after infection with *B. burgdorferi.*

7. Possible New Borrelial Syndromes

In the southern United States, where Lyme disease is not endemic, a tick-related erythema migrans-like rash has been recognized.[40] The tick associated with this entity, known as southern tick-associated rash illness (STARI), is *Amblyomma americanum* or the Lone Star tick. It is generally described as a very mild illness, usually consisting of rash without systemic manifestations such as fever or the multitude of complaints described in Lyme disease. Currently, as STARI is defined by the rash it produces. It has been found to be a distinct illness from Lyme disease as patients are test negative for Lyme disease by all accepted methods. In a comparison between patients with EM rash in Missouri and New York, the appearance of rash was earlier in patients from Missouri; they were less likely to have multiple lesions and the lesions were generally smaller and more likely to have central clearing.[118] *Borrelia burgdorferi sensu stricto* is not found in the tissues of those affected by culture or PCR. Another borrelia, *B. lonestari* has been suggested as a possible cause of STARI. *A. americanum* ticks in the southern and south central United States have been found to contain *B. lonestari* DNA.[10] In a single instance, a tick identified as *A. americanum* was detached from the center of an erythema migrans rash in a man who lived in New York and had recently traveled to Maryland and North Carolina. Both the tick and a biopsy from the rash contained DNA from *B. lonestari.* No evidence of *B. burgdorferi* was found from either source. However, a recent study in Missouri, 30 patients with EM rash had skin biopsies performed, none of which yielded DNA for either *B. lonestari* or *B. burgdorferi*.[117] The cause of STARI should be considered unknown at the present time.

Recently in Europe there was a case report of a more severe illness caused by a Borrelia previously not known to be pathogenic. *Borrelia lusitaniae* has been found in *Ixodes* ticks in coastal North Africa and Portugal and is implicated in a chronic rash with associated symptoms (headache, cardiac rhythm disturbances, and paresthesias) in a Portuguese woman. The organism was cultured from a skin lesion.[115]

8. Diagnosis

Early Lyme disease with a classic EM rash in a person with tick exposure in an endemic area is strictly a clinical diagnosis and requires no laboratory testing.

There are several methods for directly or indirectly detecting the presence of Borrelia from tissues or fluids. Cultures and PCR directly detect the presence of *B. burgdorferi* or its DNA. However, due to the difficulties with using these tests in a clinical setting, the vast majority of cases are diagnosed by serologic testing. There are a great number of laboratory tests available to the clinician and laboratory technologist, so great care must be taken to order and interpret these tests appropriately. The FDA has given approval to over 70 serologic assays alone.[61] Unfortunately inter-test reliability and even intra-test reliability in different laboratories remain a significant issue.

Most laboratories rely on enzyme-linked immunosorbent assay (ELISA) testing as the initial test. Depending upon the cutoff values employed, its sensitivity approaches 90%, with a specificity of 72%.[107] A negative test, especially in a setting with a low pretest probability makes the diagnosis of Lyme disease very unlikely. ELISA testing can have false-positive results due to cross-reactivity to other spirochetes such as *Treponema pallidum* or *Leptospira interrogans*. Patients with prior exposure to other borrelial illnesses such as relapsing fever may also test positive. In addition, autoimmune diseases such as Lupus may trigger a false-positive result with ELISA. With indeterminate or positive ELISA results, a follow-up Western blot is generally performed in order to rule out these false-positive results. The Western blot detects specific proteins or peptide segments rather than intact organisms and has a higher specificity than does standard ELISA. Both ELISAs and Western blots can be performed for IgM (early) and IgG (late) antibodies. Current recommendations suggest a cutoff of two out of three antigens positive for IgM testing and five out of ten antigens for IgG testing.[18] Of note, in patients with untreated disease for longer than 1 month, a positive IgM alone in the absence of a positive IgG test should be interpreted as a negative test. IgM testing is more frequently prone to result in false-positive testing.

Newer generation ELISA tests using synthesized or recombinant antigens such as the C6 peptide antibody assay are showing some promise in improving sensitivity and specificity of detection. The C6 ELISA tests for levels of IgG against a conserved region of the VlsE protein. This peptide evokes a positive IgG response as early in disease as IgM in traditional ELISAs and likely has fewer false positives.[51] Additionally, the C6 ELISA can be used in those patients who have previously been vaccinated with the new withdrawn OspA vaccine.[51] The epitope is conserved in *B. garinii* and *B. afzelii*, so it may be an appropriate test for patients in Europe where testing is complicated by the presence of multiple strains with differing reactivity to standard ELISA tests. While some studies show very good sensitivity and specificity,[63] the use of the C6 assay alone without confirmatory testing is not yet considered standard practice.

Great care must be taken when considering whether to send samples for serologic testing. It has been calculated that if the pretest probability of Lyme disease is <0.2, then laboratory testing is unlikely to provide useful results and in fact is more likely to be a false positive than true positive.[107] Therefore, the clinician should have a solid clinical suspicion (e.g., unexplained oligoarthritis and exposure to an endemic area, etc) before ordering these studies. In highly endemic areas, the absence of EM rash cannot be used to completely rule out Lyme disease however, and serologic testing can be helpful diagnosing conditions felt to be due to Lyme disease.

9. Special Considerations

9.1. Pregnancy

Congenital Lyme disease appears to be a rare phenomenon. In 1986, researchers [50] reported 19 cases of maternal infection by *B. burgdorferi* between 1976 and 1984. Thirteen of these women were given antibiotic treatment and five of the pregnancies resulted in adverse outcomes, including cortical blindness, syndactyly, and intrauterine death. In none of these cases was the cause directly attributed to the spirochete, but the high frequency of adverse events was noted. There have been reports of transplacental passage of *B. burgdorferi* to the fetus, and in at least one case, this occurred despite maternal treatment with oral penicillin.[113] One such case resulted in a congenital cardiac defect,[87] although again the cardiac defect could not be directly attributed to the intrauterine infection.

Several large studies have failed to conclusively show an association between maternal infection and adverse neonatal outcomes.[24,47,64,104] In the study by Nadal et al., of 12 women who were seropositive, the single mother with clinical Lyme disease had a neonate with a ventricular septal defect. Silver[91] provides a review of the studies and concludes that Lyme disease in pregnancy has a rather benign course.

Current recommendations are to treat infected pregnant women with the same treatment that would be recommend if the patient were not pregnant with the exception that doxycycline should be avoided. In a very small prospective study, breast feeding by symptomatic mothers with Lyme disease did not result in any adverse outcomes.[120]

9.2. Immunosuppression

There are currently no reports to suggest that immunosuppressed patients (HIV, chemotherapy, transplantation,

splenectomy) have more severe courses of Lyme disease than immunocompetent patients or have a lower rate of response to antibiotics.

9.3. Co-infection

Ixodes ticks may carry other bacteria or viruses that may be transmitted to humans along with *B. burgdorferi*. Ticks in the northeastern and Midwestern United States are frequently co-infected with *Babesia microti* and/or *Anaplasma phagocytophilum*. In one study, for instance, in New Jersey, DNA analysis of ticks showed *B. burgdorferi* and *Babesia microti* co-infection in 1.9% of ticks harvested.[1] Similar rates were found in the upper Midwest by analyzing serologic evidence of co-infection in humans.[57] In contrast, in the highly endemic areas of Connecticut and Rhode Island, 11% of subjects had serologic evidence of Lyme disease and *Babesia* co-infection.[42] There are limited studies that suggest that infection with more than one of these organisms may result in a more severe course for Lyme disease; however, the differences, if they exist, are typically small. Tick-borne encephalitis is a viral disease carried by *Ixodes* ticks in Europe and Asia and can cause severe neurologic problems. Interactions with *B. burgdorferi* infection have not been reported.

10. Prevention

Because Lyme disease is spread by ticks, the simplest preventive measure is tick avoidance. One risk factor for exposure to ticks is yard size. Yards larger than ½ acre are more likely to be wooded and to supply habitat for ticks and their mammalian hosts.[53] People who spend 30 hours per week or more engaged in leisurely outdoor activities are significantly more likely to become seropositive for Lyme disease than controls. The use of clothing to prevent ticks having access to skin is recommended. Long-sleeved shirts and long pants tucked into socks may be beneficial. The use of light-colored clothing makes ticks more visible and easier to remove and to serve as a warning of local tick infestation. The use of whole body checks after exposure to areas where ticks are felt to be present and during warm weather is advised, as transmission of *B. burgdorferi* is felt to be low in the first 24–48 hours of attachment.

Also advisable as part of personal protection against tick bites is the use of insect repellants. DEET (N,N-dimethyl metaloluamide)-containing formulations have been the standard repellant in the United States for many years. It is available in various concentrations from 5% up to 100%, with higher concentrations having more prolonged protection. It has been shown to be a safe and effective repellant against mosquitoes, ticks, chiggers, and biting flies. In Europe and Australia, the repellant Picaridin (KBR 3023) has been in use for many years and is also a safe and effective mosquito repellant.[109] Less information is available about its effectiveness against ticks. In a South African study[78] Picaridin was found to have limited effectiveness against *Amblyomma hebraeum* (the vector in African tick bite fever). Permethrin, which is not a repellant, but rather an insecticide (acaricide) is perhaps the most effective means of preventing tick bites.[20] Permethrin is to be applied only to clothing and not to skin.

The population of ticks in residential areas can be curtailed by simple landscaping procedures such as creation of a buffer zone of mulch between the grassy yard and the abutting areas of woodland and scrub, where ticks reside. The removal of branches and leaves and once or twice yearly application of acaricides can significantly reduce exposure to ticks. Application of carbaryl (an acaricide) to residential yards can be nearly 100% effective against *Ixodes* ticks, with residual cidal effects of up to 60 days.[93] Another acaricide, deltamethrin has been demonstrated to reduce both *Ixodes dammini* and *Amblyomma americanum* ticks when applied to the wooded periphery of residential sites.[88]

Another approach to controlling the tick vector of Lyme disease is the application of acaricide to the mammalian hosts, such as the white-tailed deer. By placing feeding stations in strategic locations, deer in the wild are attracted to food such as whole kernel corn. In order to access the feeding bin, the deer must rub up against foam rollers that have been impregnated with acaricide.[74]

In 1998 a human vaccine against *B. burgdorferi* was licensed. Named LYMErix, this vaccine consisted of a recombinant OspA lipoprotein. This vaccine was unique in that it acted by a human antibody-mediated effect against *B. burgdorferi* that took place in the tick vector rather than in the human host. OspA is up-regulated in the tick and is generally not expressed in mammals. After a series of three injections, the efficacy against Lyme disease was 76%. It was also established to be a safe vaccine, with the chief side effects consisting of local injection site reaction, myalgias, and a small number of cases having fever (2%).[39,97] Despite the attributes of good efficacy and safety, the vaccination was withdrawn from the market in 2002 by the manufacturer due to small demand. This low demand was partly the result of claims that the LYMErix vaccine could theoretically cause autoimmune arthritis through molecular mimicry of LFA-1 by OspA. Large studies have never supported an association of the vaccine with arthritis. Recently, trials of a new OspA vaccine which has been engineered to remove the LFA-1 cross-reacting epitope have started in Europe.

The use of antibiotic prophylaxis in a person found to have and attached tick is somewhat controversial. One study performed in New York state in an area known to have very high rates of Lyme disease showed that treatment with single oral dose of doxycycline was efficacious in preventing the development of Lyme disease.[65] Another slightly smaller study in southeastern Connecticut failed to show any difference in risk of infection of children given amoxicillin prophylaxis.[90] The routine use of antimicrobial prophylaxis is not recommended by the Infectious Disease Society of America (IDSA).[119] In those patients who discover an attached tick, careful observation is advised for signs of Lyme disease, or other tick-borne illnesses such as babesiosis or anaplasmosis. The use of prophylactic antibiotics should be restricted to patients in endemic areas who present with a *Ixodes* tick bite where the tick has been attached for greater than 36 hours.

11. Treatment

Treatment of Lyme disease is dependent on the clinical manifestations present. The following treatments are extracted from the Infectious Diseases Society of America (IDSA) practice guidelines for the treatment of Lyme Disease.[116] In patients with known or suspected tick bites who manifest with signs and symptoms of Lyme disease, especially with a rash consistent with erythema migrans, oral treatment should be initiated. Doxycycline 100 mg twice daily (in patients >8 years of age) for 14 days (range of 10–21 days) or amoxicillin 500 mg three times daily for 14–21 days have been recommended as first-line therapy by expert panels. The use of doxycycline is preferred in adults as it is also effective against *Anaplasma phagocytophilum* and has good penetration into the CNS. Cefuroxime (500 mg twice daily) for 14–21 days has also been shown to be very effective. Doxycycline should not be taken by pregnant or breast-feeding women, or children less than 8 years old. Newer macrolide antibiotics are also effective, but the treatment failure rate is higher than for first-line regimens.

For Lyme arthritis, oral or intravenous antibiotics may be used. Oral doxycycline is again the preferred drug, as it is well absorbed, inexpensive, and efficacious. It also has some inherent matrix metalloproteinase inhibitory properties, thus acts as an anti-inflammatory agent. Amoxicillin or cefuroxime is alternative agent as noted above. The recommended length of treatment is a 28-day course. Some experts advocate an additional 28-day course of PO or IV antibiotics when patients have not responded to the initial course. PCR testing of the joint fluid may be helpful in confirming clearance of the organism and guiding length of therapy. Patients with negative PCR testing who have not improved with antibiotic therapy often respond to traditional treatment for rheumatoid arthritis. Anecdotal responses to methotrexate and anti-TNF therapies have been described.

Intravenous therapy is often recommended for patients with neurological or cardiac complications of Lyme disease. The exceptions are those with neurological disease limited to facial palsy without meningitis and cardiac disease limited to first or second degree AV block. These patients may be treated with the oral regimens described for EM. Some experts recommend routine lumbar puncture for all patients with facial nerve palsy due to Lyme disease, while others reserve lumbar puncture for those with headache, neck stiffness, or other signs of CNS involvement. For patients with inflammatory changes in the CSF, intravenous penicillin (18–24 million units iv daily, divided q 4 h), cefotaxime (2 g iv q 8 h), or the preferred regimen of ceftriaxone (2 g once daily) should be initiated. There have been no trials aimed at the most appropriate treatment for Lyme carditis, the current guidelines are based on expert opinion, but have been established as standard of care. Hospitalization and cardiac monitoring are recommended for symptomatic patients with atrioventricular heart block or Lyme myocarditis. Initial therapy generally should be intravenous β-lactam antibiotics such as ceftriaxone. Once the heart block is considered stable, and if temporary pacemaker is not required, the treatment can be transitioned to oral antibiotics for a total course of 14–21 days.

For those patients with acrodermatitis chronica atrophicans, data suggest that a 21-day course of the oral antibiotics used for erythema migrans is generally sufficient. No controlled trials have been conducted comparing oral to intravenous therapy for this condition.

While the organisms are sensitive to killing by multiple antibiotics and the development of resistance to antibiotics approved for treatment of Lyme disease has not been documented, there is now growing evidence that *B. burgdorferi* may persist in animals following administration of antibiotics. Straubinger et al. infected dogs with *B. burgdorferi* and treated with different regimens of amoxicillin, doxycycline, azithromycin, or intravenous ceftriaxone.[100,101,102] Although skin punch biopsy culture rapidly turned negative in animals within 2 weeks of initiation of antibiotics, 17% of the antibiotic-treated animals were culture positive for *B. burgdorferi* on post-mortem tissue cultures >3 months after antibiotic therapy. In addition, at least one PCR of a skin punch biopsy or post-mortem tissue was positive for all but one animal (11/12 total—six treated with doxycycline and six with amoxicillin) beyond 80 days after therapy. Studies have shown that positive testing for *B. burgdorferi* DNA by PCR correlates well with persistence of live organisms,[49]

however, this may not be true in all cases and PCR has the potential to recognize DNA from dead or dying bacteria. Antibiotic-treated dogs had fewer symptoms than control-treated dogs although several had mild arthritis. Interestingly, antibody titers declined in the antibiotic-treated dogs despite the continued presence of bacteria as detected by culture or PCR, suggesting that a minimal threshold of organisms is required to maintain antibody titers or that the bacteria that remain after antibiotic therapy express antigens not detected by the ELISA assay used.

Recently Bockenstedt et al. and Hodzic et al. reported on the persistence of *B. burgdorferi* after antibiotic treatment in mice.[8,30] Dr. Bockenstedt's group administered either ceftriaxone or doxycycline to mice 30 days after infection. Mice were treated for 30 days with antibiotics. At 1 month and 3 months after treatment, the presence of *B. burgdorferi* was tested by xenodiagnostic feeding of uninfected nymphal *Ixodes* ticks on the mice. About 40% of mice in the both the ceftriaxone- and the doxycycline-treated groups tested positive by xenodiagnosis in that spirochetes could be observed in ticks by direct fluorescent antibody microscopy (DFA) or their DNA detected by PCR. Dr. Stephen Barthold's group performed similar experiments but also compared the effects of early (within 3 weeks of infection) and late (4 months after infection) antibiotic therapy.[30] With the initiation of early therapy, none of the antibiotic-treated mice were positive on culture or PCR of tissues. However, one of three mice was positive by xenodiagnosis. In mice treated late after infection, and evaluated 1 month after treatment, tissues from all of the antibiotic-treated mice remained PCR positive (but culture negative) and 37–60% of mice were positive by xenodiagnosis suggesting that the timing of antibiotic therapy plays an important role in antibiotic-mediated eradication of Borrelia. At 3 months after infection, tissues from two of five antibiotic-treated mice were positive for *B. burgdorferi* by PCR and 40% were positive by xenodiagnosis. Quantitative PCR revealed that spirochete numbers in the mice with persistent infection after antibiotics were significantly lower. Similar to the dog experiments, serum antibodies against *B. burgdorferi* also decreased in the antibiotic-treated compared with saline-treated mice despite the continued presence of the organism. When ticks that fed on antibiotic-treated mice were used to subsequently feed on immunodeficient mice (to increase the chance of establishing infection), 89% of the mice showed evidence of acquiring *B. burgdorferi* by PCR.

Data for persistence of *B. burgdorferi* after antibiotic therapy in humans are less clear. There have been multiple reports of relapses/failures of antibiotic therapy in patients with Lyme disease; however, some of these were not culture proven or were using antibiotics not currently recommended for the treatment of Lyme disease.[68,79,80,103] Certain antibiotics do seem to be less effective clinically (e.g., erythromycin) despite in vitro activity.[114] PCR from synovial tissue of patients with Lyme arthritis have been reported to remain positive after antibiotic therapy.[81] PCR from synovial fluid after antibiotic therapy, which could detect either live or dead bacteria, can remain positive after 1 month of antibiotic therapy, but is generally cleared after 1–2 more months of antibiotics. Cultures of synovial fluid are uniformly negative both before and after antibiotics, likely due to the limitations of culture. Strle et al. have reported that 31% of patients with a positive culture from an EM lesion remain positive 3 months after a 14-day course of doxycycline; similarly 6% of patients treated with azithromycin remained positive by culture.[103] Hunfeld et al. have reported that skin biopsies of patients with culture positive EM remained *B. burgdorferi* positive by culture 2 months (range 1.3–3 months) after antibiotic therapy in 1.7% of patients (19 out of 1148).[34] Spirochete persistence was not accounted for by the development of resistance to the antibiotic. However, there have been concerns raised about this study, because the strains of *B. burgdorferi* recovered in some cases differed from those found in the EM lesion prior to antibiotic therapy. Whether persistence of *B. burgdorferi* after antibiotic treatment could be a cause for persistent symptoms in some patients remains unknown.

12. Conclusion

While research over the last several decades has greatly increased our knowledge about Lyme disease, progress is still needed in the areas of reliable diagnosis and prevention. Recent advances in the understanding of how *B. burgdorferi* interacts with its various hosts may lead to new concepts in testing and treatment of human disease and control of infection in the wild-life reservoirs.

CHAPTER 24

Meningococcal Infections

Robert S. Baltimore

1. Introduction

The meningococcal diseases[1] represent a spectrum of illness caused by *Neisseria meningitidis* (Table 1). Although sporadic endemic cases occur throughout the world, massive, devastating epidemics tend to reflect conditions of crowding, mobilization, and enclosed institutional populations. In recent years outbreaks have also been associated with large religious gatherings, especially the Hajj. Such outbreaks tend to be extraordinarily disruptive, especially because of the fear and fright that they induce in the affected populations. Among civilians, children are most often attacked, with mortality rates of 80–90% having been noted in some epidemics that occurred before effective therapeutic agents became available. In the past the disease was also known as "cerebral spinal fever" and "epidemic cerebral spinal meningitis," as well as by other names. Mobilization for war, with the induction of many young men into crowded military camps, has generally been accompanied by outbreaks. Also, in recent years there has been awareness of outbreaks as well as frequent sporadic meningococcal infections among college freshmen, who also represent a mix from many diverse origins, in dormitories and other sometimes crowded living quarters on many campuses. Generalized outbreaks among the military do not arise de novo, but may reflect what is occurring in the associated civilian populations. The development of meningococcal capsular polysaccharide vaccines, and more recently conjugate meningococcal vaccines, has had a significant effect on prevention of military epidemics of meningococcal epidemics, and now its impact on civilian disease is, becoming, realized.

Robert S. Baltimore • Departments of Pediatrics and Epidemiology and Public Health, Yale University School of Medicine, New Haven, Connecticut 06520-8064, USA.

In the first edition of this book, this chapter was written by the late Harry Feldman, MD. Substantial historical and epidemiological data come from his original manuscript.

[1] In this chapter, the term *case* or *disease* refers to any instance of meningococcal infection other than asymptomatic pharyngeal (carrier).

2. Historical Background

Clinical meningococcal disease was first described by Vieusseux[(1)] in 1805 during an outbreak in the vicinity of Geneva, Switzerland. A year later, Danielson and Mann[(2)] reported a small, probable epidemic of meningococcal meningitis in Medfield, Massachusetts. This paper appeared in a publication known as the *Medical and Agricultural Register* and was entitled "The history of a singular and very mortal disease, which lately made its appearance in Medfield." The nine fatal cases were so similar that only one was fully described; all occurred during March. Weichselbaum[(3)] identified meningococci in the spinal fluids of patients in 1887.

During the 19th century, possible epidemics occurred in countries throughout the world in 1805, 1837, 1854, 1876, and 1896. In the 20th century, major outbreaks were noted during World Wars I and II, and subsequent to the latter, there was a massive, lengthy outbreak in sub-Sahara Africa,[(4)] a more localized one in Morocco,[(5)] and another affecting more than a quarter of a million people in Brazil,[(6)] as well as others in Finland[(7)] and among American military inductees during the Korean and Vietnam mobilizations. Smaller, localized outbreaks have occurred from time to time in various institutions and localities. In the course of the many studies that were conducted during World War I, Gordon[(8)] identified four serological types of meningococci: I, II, III, and IV. In 1953, Branham,[(9)] as the result of her careful, meticulous studies, labeled the different serogroups A, B, C, and D. She believed that organisms of group A were those principally responsible for epidemics and that sporadic cases

tend to be antigenically heterogeneous as the result of infections with groups B and C. Slaterus[10] subsequently demonstrated three additional meningococcal serogroups (X, Y, and Z), and then Evans et al.[11] identified serogroups W-135 and 29-E from US Army isolates. Subsequently, groups H, I, K, and L have been described[12,13] In the 1970s and 1980s, groups Y and W-135 became recognized as frequent causes of invasive meningococcal infections.[14–17]

An enormous step forward was made early in World War II when it was learned not only that sulfadiazine was effective in the treatment of cases but also that small doses eliminated the organism from the nasopharynx.[18–21] When sulfadiazine was administered on a mass basis to a closed population, cases of disease disappeared almost instantaneously and the carrier rate was reduced to near-zero levels. Thus, an effective, simple, relatively inexpensive control system for preventing meningococcal disease and curtailing epidemics was provided. Unfortunately, this was found to be ineffective in 1963 by Millar et al.[22] during several unsuccessful attempts to control the disease among naval recruits in San Diego. It was learned then that many disease-related strains were resistant to large concentrations of sulfadiazine, and thus that the sulfonamides could no longer be used effectively for the prevention or control of epidemics.[23] In a number of subsequent trials conducted under the auspices of the Armed Forces Epidemiological Board, no substitute chemotherapeutic agent was found, although the satisfactory treatment of actual cases could be accomplished with large doses of penicillin. The latter was quickly adopted as routine therapy for both military and civilian use. Eventually, in the 1970s, rifampin was adopted as the recommended chemoprophylactic agent for close contacts of cases,[24] and currently a number of agents are useful for prophylaxis (Table 2).

In the early 1970s, a vaccine for serogroups A and C was developed.[25,26] In 1981 a tetravalent vaccine (Menomune®) containing the capsular polysaccharides of serogroups A, C, Y, and W-135 was marketed commercially and is available today for the military and individuals considered to be at exceptional risk of contracting meningococcal infection.

In the late 1990s there was considerable concern about the risk of meningococcal disease in freshman college students. This led to strong recommendations for routine immunization of this group with meningococcal polysaccharide vaccine.

In January 2005 a tetravalent meningococcal conjugate vaccine (MCV4) containing the capsular polysaccharides from serogroups A, C, Y, and W-135 (4 μg each) conjugated to 48 μg of diphtheria toxoid was approved in the United States for immunizing people 11–55 years

Table 2. Chemoprophylaxis for Contacts of Patients with Infection Due to *Neisseria meningitidis*

Drug (Generic Name)	Age of contact	Dose/regimen/duration
Rifampin (orally)	Adult	600 mg every 12 h for 2 days
	1 month to 12 years	10 mg/kg every 12 h for 2 days
	Less than 1 month	5 mg/kg every 12 h for 2 days
Ciprofloxacin	Adult	500 mg single dose
Sulfadiazine (orally) (only if index case is known to be susceptible)	Adult	1 g every 12 h for 2 days
	1–12 years	500 mg every 12 h for 2 days
	Less than 1 year	500 mg every 24 h for 2 days
Ceftriaxone (intramuscularly)[a]	15 years or older	250 mg as a single injection
	Less than 15 years	125 mg as a single injection

[a]Ceftriaxone has shown to be very effective for elimination of meningococcal carriage in contacts of cases with group A meningococcal strains but there is a lack of data on reduction of the rate of secondary cases.[144,145]

of age. In the United States this vaccine is currently recommended for routine immunization of adolescents (see Sections 9.3 and 9.3.1).

3. Methodology

3.1. Sources of Mortality Data

The principal sources of mortality data on meningococcal diseases are local and federal health agencies such as, in the United States, local and state health departments and the Centers for Disease Control and Prevention (CDC) through the *Morbidity and Mortality Weekly Report* (MMWR). In addition, there are publications of the World Health Organization (WHO) and various military sources, but these deal only with the populations that they serve. By and large, mortality data reflect the incidence of the disease, although they can be affected by a number of variables, especially the level of health care available, age, and the rapidity with which treatment can be instituted. The level of completeness of mortality data is reflected to a great extent by how well public health reporting is organized and whether adequate laboratory facilities are available for identifying individual disease-causing agents.

3.2. Sources of Morbidity Data

The disease is generally reportable, and because of the fear that it engenders, reporting is reasonably complete and tends to mirror the availability of proper laboratory facilities to identify etiologic agents in individual cases.

Prevalence and incidence data are regularly supplied in the CDC MMWRs and in the *Annual Summary* of the same publication (Figure 1).[27] Additional sources of information are the *WHO Weekly Epidemiological Record* and the *Canada Diseases Weekly Report*. Other data may be found in the published reports describing individual outbreaks. The latter generally observe geographic limitations, whereas the MMWR considers the United States as a whole. Additional data may be found in the reports of various state and local health departments.

3.3. Surveys

Carrier surveys were often conducted among military populations, whereas among civilians, case contacts are often cultured, especially in schools and families. Carrier surveys are primarily of the posterior nasopharyngeal carrier state. In recent years, carrier surveys have been deemphasized.

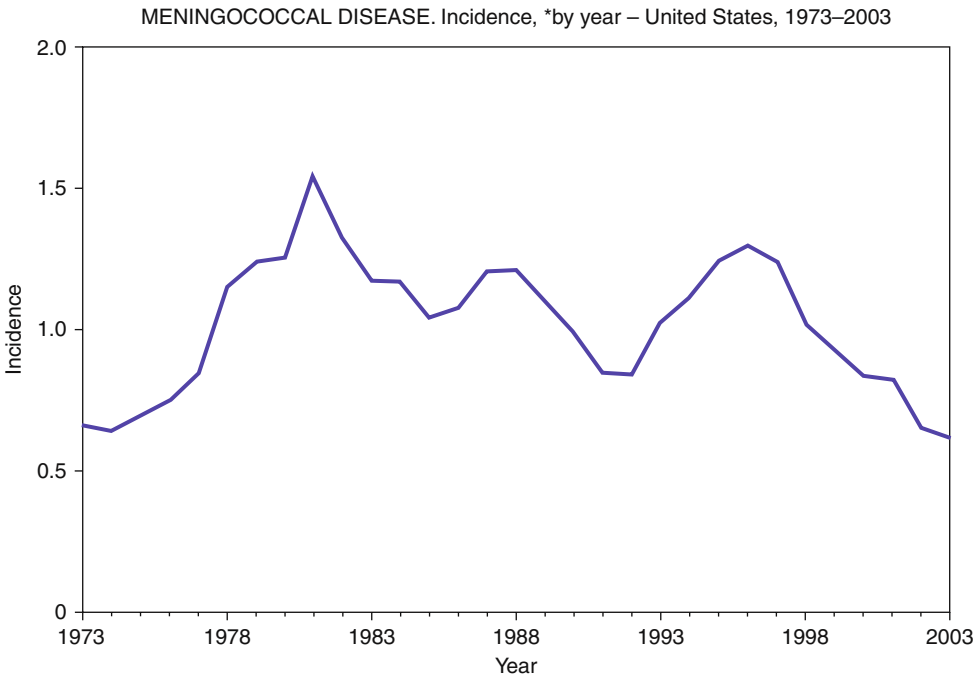

Figure 1. Meningococcal Disease, by year United States, 1973–2003. From reference (27).

This is because they generally yield little information about the immune state of the population or the introduction of new, virulent meningococcal strains. These appear to be more predictive of risk for an outbreak. Serological surveys, other than in vaccination trials, have not been used generally because the available methods do not lend themselves to mass application and, furthermore, because one would have to test for antibodies to all known serogroups.

In the United States, the CDC has sponsored special surveys of meningococcemia and meningitis. These usually target representative states and then are extrapolated to calculate rates for the whole country.[28–30] In 2005 the British Health Protection Agency has published meningococcal disease rates to demonstrate the reduction of serogroup C disease following widespread use of the conjugate meningococcal C vaccine.[31]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. *N. meningitidis* is a fastidious, gram-negative diplococcus that grows best on enriched media such as blood or chocolate agar and in the presence of increased CO_2. The latter is especially useful for primary isolation. The organism may be isolated from all body areas and orifices. When *N. meningitidis* is sought in places where competing bacteria are prominent, it is best to use Thayer–Martin medium,[32] which consists of chocolate agar to which several antibiotics inhibitory for gram-negative, gram-positive, and yeast-contaminating organisms have been added. This medium is especially useful for the identification of meningococci in nasopharyngeal secretions and cultures from rectal swabs. Organisms may be cultivated frequently from the male urethra, the cervix, the conjunctivae, and in cases of arthritis, from purulent septic joint fluids. In patients with meningococcal bacteremia or meningitis, cultures of the blood are usually positive, as are those of spinal fluid. Meningococci may be demonstrated in Gram-stained smears from petechiae or the buffy coats of those with severe sepsis. Cultures from normally sterile fluids such as blood, cerebrospinal fluid (CSF), or joint fluid may be cultivated on regular blood or chocolate agar rather than Thayer–Martin medium, as inhibition of normal flora is not necessary. The same is true of subcultures of individual colonies from primary isolation media.

The organism ferments glucose and maltose but not lactose. Sometimes the fermentation of glucose is slow and may require 48 h or more of incubation. More rarely, glucose may not be fermented at all. Meningococci are oxidase positive, and this reaction may be helpful in the recognition of colonies on plates with mixed flora. The use of Thayer–Martin medium usually removes the latter requirement. The organism does not grow at room temperature or on simple media such as nutrient agar.

Meningococcal polysaccharide antigens can be detected in body fluids or in the supernatant of growing cultures. Latex beads coated with meningococcal antisera are available commercially. They will agglutinate in the presence of soluble meningococcal antigens.

In recent years polymerase chain reaction has been reported to be useful for the diagnosis and serologic determination of *N. meningitidis* from clinical samples.[33–36] Advantages of this technique are theoretical increase in sensitivity over culture and ability to identify the organism in samples in which the organism has been killed because the patient was receiving antibiotics before the sample was taken. The specificity of PCR for *N. meningitidis* is still being studied. Differences in results from various studies may have to do with different genes included in the primers.

3.4.2. Serological and Immunologic Diagnostic Methods. While meningococci contain several antigens, the group-specific one is a polysaccharide that is readily detected by slide agglutination. This usually works well with isolates from body fluids of actual cases. Often, throat and sputum isolates are rough and tend to agglutinate spontaneously in saline. They are also agglutinated in normal rabbit serum and all, or nearly all, group-specific antisera. Such organisms are usually identified as "saline agglutinable." Slide agglutination can be performed rapidly, but requires pure cultures and active antisera. These can be done in fairly large numbers on large plates, and thus lend themselves well to population studies and epidemiological investigations. Organisms of serogroups A and C are encapsulated; when freshly isolated or still in original spinal fluids they may be shown to "quell" with potent antisera. This reaction can be used for rapid identification, especially of organisms in spinal fluid. For serogrouping in a reference laboratory, the hemagglutination inhibition test has been reported to be both highly sensitive and specific.[37] As mentioned in Section 3.4, polymerase chain reaction can be used not only for detection *of N. meningitidis* but also for serogrouping, using serogroup-specific primers such as capsule biosynthesis genes.[33–36]

4. Biological Characteristics of the Organism

Under the special conditions that lead to epidemics, encapsulated (virulent) organisms are transmitted rapidly from person-to-person, probably in respiratory droplets. They tend to localize primarily in the posterior nasopharynx.

Thus, attempts to determine the extent, or degree, of infection of a population at any given time require surveys of the posterior nasopharyngeal prevalence of the organism. This is best achieved with a bent wire swab that is passed up behind the uvula, wiped across the posterior nasopharynx, withdrawn, and immediately plated on Thayer–Martin chocolate agar. The warmed plates should be placed in an incubator as soon as possible thereafter. If the incubator contains CO_2, no other container needs to be used. If no CO_2 incubator is available, then the newly inoculated plates should be put into candle jars. The spontaneous extinction of the candle flame will indicate that the CO_2 content is elevated; when the jar is put at 37°C, suitable growth for further subinoculation and isolation should appear overnight.

Most of the major epidemics of this century have been caused by group A meningococci, although the massive Brazilian epidemic of the 1970s began as a group C outbreak that was then displaced by group A organisms. Localized outbreaks due to meningococci of groups B, C, W-135, or Y have been noted, but more often than not, they are present in sporadic cases.

4.1. Serotypes and Serogroups

Meningococci are grouped according to their polysaccharide capsule antigens into serogroups A, B, C, D, H, I, K, L, X, Y, Z, W135, and 29E. In the United States serogroup A is very rare. Serogroups B, C and Y have been responsible for approximately one-third of cases each, in recent years. In young children under 1 year of age serogroup B is more common, accounting for over 50% of meningococcal disease.[38] The next most common serogroups were W135 and Y, accounting for 3 and 2% of isolates, respectively.[38,39] Fewer than 1% are serogroup A. In contrast, in sub-Saharan Africa and Scandinavia serogroups A and C are predominate. Serogroup W-135, previously found only in carriers, was found to cause occasional cases of meningococcal disease in the 1970s and in recent decades has been associated with outbreaks in Asia, especially associated with the gathering at the Hajj.[14–17]

Meningococci can also be typed according to protein and lipo-oligosaccharide (LOS) antigens. The outer membrane of *N. meningitidis* contains LOS, similar to the lipopolysaccharides of gram-negative bacilli. The outer membrane proteins (serotypes) are shared by isolates from different serogroups. These protein antigens are recognized by the human immune system and they may be developed into effective vaccines.

A number of systems have been devised for typing meningococci.[40,41] Three methods were reported in the 1970s. Zollinger and Mandrell[42] used both outer membrane protein and LOS to serotype meningococci, but with specific absorptions they could type according to outer membrane proteins. Subsequently, Apicella[43] also used LOS to serotype group B meningococci. Frasch and associates[44] subsequently proposed a scheme based on electrophoretic mobility in sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) gels of two major proteins and LOS into 21 serotypes, bringing together schema of several laboratories into a unified scheme. Most of these 21 types can be distinguished by monoclonal antibodies.[44] Multilocus enzyme electrophoresis is a more recently described method used by a number of laboratories. Achtman[45] has utilized mobility of bacterial isoenzyme proteins in an electrophoretic field and typed epidemic strains and has traced clones of serogroup A that have spread from country to country. Ashton et al.[46] used typing by monoclonal antibodies to differentiate serogroup B isolates from Canada using an enzyme-linked immunosorbent assay (ELISA) technique. These techniques are not generally available for typing strains from individual cases, but when applied by research laboratories can provide additional information for epidemiological studies of transmission, relationships among cases, or the presence of an epidemic strain in a geographically defined area.[41,45–48]

4.2. Antibiotic Susceptibility

The susceptibility and resistance of meningococci to various chemotherapeutic and antibiotic agents have played a significant role in the treatment of individual patients and, perhaps more important, in the management of epidemics. The new era began in 1941 with a publication by Dingle et al.[49] that demonstrated that sulfadiazine was effective in the treatment of meningococcal meningitis. This finding was subsequently supported by others.[50] It was also found during these clinical studies that meningococci were eradicated from the posterior nasopharynx within hours after treatment was initiated. Then came a number of trials in the military in which it was observed that small doses of sulfadiazine given for short periods of time were sufficient to eradicate the carrier state.[18–20,51] When 1 g was given twice daily for 2 days to military recruits en masse in a given installation, not only was the carrier rate reduced to negligible levels but also the effect on disease was almost instantaneous. This simple control measure was instituted as a routine in all military installations as well as in civilian populations with excessive numbers of cases or to prevent secondary cases within households.

All this came to an end in 1963 when such control measures seemed to have no impact on the occurrence of

cases at the San Diego Naval Training Center.[22] Investigation of this event led to the demonstration by Millar et al.[22] that resistance to sulfonamides was widespread throughout the United States in both military and civilian populations. Initially, this seemed to be limited to serogroup B and C meningococci, whereas group A infections that were occurring in Africa and in some parts of the Mediterranean Basin continued to be susceptible. However, in a widespread group A epidemic in Morocco,[5] the causative organisms were found to be significantly resistant to sulfadiazine. This was soon confirmed in other parts of the world and led to the recommendation that cases be treated with large doses of penicillin. This has proven to be successful. Subsequently, rifampin or minocycline or a combination thereof has been demonstrated to reduce carrier rates.[52–55]

For decades, penicillin has been considered to be the antibiotic of choice for treatment of meningococcal disease, although other semisynthetic penicillins and cephalosporins and chloramphenicol are also effective. Beginning in the 1980s there have been reports of meningococcal isolates with reduced susceptibility to penicillin. While susceptible strains have a minimum inhibitory concentration (MIC) of 0.03 μg/ml to penicillin, relative resistant strains with an MIC of 0.1–1.28 μg/ml have been reported from Spain,[56] England,[57] South Africa,[58] Canada,[59] and the United States.[60,61] While an estimated 4% of meningococcal isolates in the United States in 1991 were relatively resistant, the clinical significance of resistance at this level is uncertain if large doses of penicillin are used for treatment.[61] Penicillin-resistant strains are generally susceptible to third-generation cephalosporins and these are frequently employed at the beginning of antibiotic therapy before the organism has been positively identified. Penicillin resistance is not due to production of penicillinase by the organism but by reduced affinity of cell wall penicillin-binding proteins (particularly penicillin-binding protein 2) for penicillin.[62] In Spain, where the prevalence of such isolates climbed to 20% in the late 1980s, the types and subtypes of these isolates were quite diverse.[48] Concerns about changes in susceptibility of meningococci to antibiotics has continued in the 2000s.[63] Since the reports showing that ciprofloxacin can be used for meningococcal prophylaxis, resistant to this agent has been reported.[64] In a recent report in which 442 international meningococcal strains were tested, elevated penicillin MIC ($\geq$12 μg/ml and $\geq$25 μg/ml) occurred in 14.3 and 8.6% of strains, respectively, and in addition 13 strains showed reduced susceptibility to tetracyclines, 2 strains had reduced susceptibility to quinolones, and 21.7% were resistant to sulfisoxazole.[65]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Information on prevalence and incidence is complicated by the multiplicity of serogroups of meningococci. Prevalence and incidence are more precisely stated and of greater value when serogroups are identified than when they are categorized under the generic term "meningococci."

In general, the rate of meningococcal disease in the United States has been 0.5–1.1/100,000.[38] Jacobson et al.[66] reported that in the United States in 1974, there was 0.60 case/100,000 population per year. As noted in Figure 1, this was a year of low incidence. Yet, despite this low incidence, the rates were 9.47 in infants less than 1 year old and 2.27 in children 1–4 years old.

In an active surveillance program sponsored by the CDC in 1978, the annual incidence of meningococcal meningitis in the United States was estimated to be 0.72 case/100,000 population. The peak age of meningococcal meningitis was 3–8 months (peak incidence 13/100,000). The peak age of meningococcemia was 6–8 months (peak incidence 5/100,000).[28] A CDC-sponsored laboratory surveillance reported an average annual incidence of 1.1/100,000 in 1989–1991.[39] The highest rate was in infants $<$4 months of age, 26.4/100,000. In 1990–1994, the rate of meningococcal meningitis averaged 0.96 cases per 100,000.[67] In the most recent report, from 1991 to 2002 the rate of meningococcal disease in infants under 1 year old was 9.2/100,000 and 62% of meningococcal disease occurred among children 11 years old or older.[38] While the rate of meningococcal disease in the United States and other Western countries is 1–3/100,000, in developing countries it is much higher, up to 10–25/100,000.[68]

5.2. Epidemic Behavior and Contagiousness

Glover,[69] in a classic report, concluded that carrier rates were most affected by "overcrowding" of sleeping arrangements. While "standard" accommodations in the British Army had been defined by a Royal Commission in 1861 as 60 ft^2 of floor space (600 ft^3 of air space and 3 ft spacing between beds) per man, this was reduced to 40 ft^2 of floor space and 400 ft^3 of air space soon after the outbreak of World War I because of mobilization pressures. At the end of the third year of the war, he found the space between beds in a distinguished unit to be less than 6 inches. Glover concluded that distances between beds were so important that he could predict the meningococcal carrier rate in a barracks by computing the distance between its beds. If the distance was 1 ft 4 in., the carrier rate would be 10%. A slight decrease

sent the carrier rate up to between 10 and 20%. If the beds were closer than 1 ft, 20% was the rate, and if the distance was less than 9 inches, a carrier rate of 28–30% was to be expected. When the recommended distance was maintained, the carrier rate rarely exceeded 5%.

"Overcrowding" (defined as less than 40 ft^2 per man) was soon followed by a sharp rise in the carrier rate, reaching its maximum in about 2 weeks. The rise was accompanied by an increase in the proportion of epidemic carrier strains. The increase of this rate among noncontact carriers to 20% meant that an outbreak was imminent. The high carrier rates could be reduced, although not as quickly as they had increased, by increasing the space between beds to $2\frac{1}{2}$ ft or more. Thus, he concluded that "to raise the carrier rate by overcrowding was both easier and quicker than to diminish it by spacing out."

In the devastating epidemic of 5,885 cases that occurred in Santiago, Chile, during 1941–1942, Pizzi[70] reported that in the area of the city where the epidemic was concentrated, the population density was seven persons per room and 2.9 per bed. The secondary attack rate overall was 2.5%, but it was 3.9% for those under 15 years of age and 1.5% among those more than 15 years of age. This experience tended to support Glover's observations.

Various studies have been reported by other authors in which no cases were seen when carrier rates were high[71] or cases were seen when carrier rates were low. Perhaps a key observation was supplied by Schoenbach,[72] who cultured 200 men in a military unit three times a week for 10 weeks. While the carrier rate averaged 41% during this period, 91% were identified at some time to be carriers. Similar, but unpublished, observations were made by Dr. Harry A. Feldman in conjunction with colleagues at the Fourth Service Command Medical Laboratory at Fort McPherson, Georgia, during the same period.

A source of great puzzlement for public health workers, epidemiologists, and microbiologists who have studied epidemics of meningococcal disease over the years has been the apparent discontinuous pattern of disease occurrence. Arkwright,[73] in a truly remarkable albeit much neglected report, concluded that

> The large number and widespread distribution of carriers and the small number of cases of meningitis compared to the population forces upon one the view that for a true understanding of an epidemic of meningitis, the total number of persons who harbour the meningococcus should be looked upon as constituting the true epidemic . . . the carriers constitute the mass of the epidemic, and those who subsequently develop meningitis are only a small accidental minority. The cases of meningitis, on account of the severity and fatality of this complication, give to the epidemic its importance, and they necessarily bulk largely in the eyes of the clinician . . . a consideration of all the evidence about carriers leads to the conclusion that the statement that cases of meningitis occur when and where carriers of the meningococcus become numerous, is a more correct way of stating the facts than by saying that many carriers occur in the neighbourhood of cases of meningitis.

The meningococcal situation parallels that of poliomyelitis, in which paralytic cases seemed to occur without rhyme or reason until the presence and importance of the nonparalytic individual was established. It was then determined that only about 1 in 100 infected individuals developed paralytic disease.[74] Maxcy[75] concluded that a similar rate occurred in meningococcal infections.

The key to the occurrence of an epidemic is the carrier or acquisition incidence rate. This has to be rapid for an epidemic to happen, since many individuals must acquire the organism for the relatively few cases to occur. It is the concentration of the latter that defines the presence of an epidemic. The key question remains, namely, what initiates the transmission speedup in a population that results in increased numbers of cases and an epidemic? While the carrier state may persist for months,[76,77] the period of communicability is unknown.

It would seem logical to infer that if there were *no* carriers, there would be no cases. This concept led many to investigate the effectiveness of sulfonamides for the elimination of the carrier state, since it had been observed early in the research on sulfadiazine treatment that organisms disappeared rapidly from the posterior nasopharynx.[18–20,51,72] Typical of reports confirming this effective measure was that of Kuhns et al.[20] A simple 2-g dose reduced the carrier rate to near zero, but the effect was prolonged when such treatment was maintained for 2–3 days.[72] Cases disappeared just as promptly.

During World War II, an epidemic in the military was defined as the occurrence of 1 or more cases/10,000 soldiers per week.[78] The epidemic that accompanied World War II can be readily seen in Figure 2, as can the relative increases noted during the Korean and Vietnam conflicts. The latter two reflect recruit outbreaks primarily, while the World War II increase was noted both in the military and in the civilians, worldwide.

5.3. Geographic Distribution

Meningococcal infections are limited to humans and have been noted throughout the world in either small circumscribed concentrations[79] of cases or widespread areas[80–84] involving whole countries (Brazil) or geographically large areas such as sub-Sahara Africa.[4] In 1948–1950, there was an epidemic of 92,964 cases with 14,273 deaths in northern Nigeria.[85] The band of countries stretching across sub-Sahara Africa from

Gambia to Ethiopia is often referred to as the meningitis belt and epidemics in this area are frequent, with rates of meningococcal disease of up to 1,000/100,000 (1%).[68] In recent years, outbreaks of meningococcal disease have occurred in Saudi Arabia at the time of the *Hajj*, presumably due both to influx of individuals who carried epidemic strains and to overcrowding. A major outbreak occurred in 1987 with a particular clone of group A that was spread by pilgrims returning from Mecca to many other countries.[45] In the early 2000s meningococcal serogroup W-135 has been responsible for the *Hajj*-associated outbreaks. Many health authorities have recommended that travelers to Mecca receive meningococcal vaccine.[86] Travelers now require meningococcal vaccine and this appears to be responsible for a current reduction in the *Hajj*-associated meningococcal risk.

5.4. Temporal Distribution

Sporadic endemic cases of meningococcal infections are encountered throughout the world at all times. Outbreaks tend to occur in various places for no discernible reason(s). On occasion, epidemics break out almost simultaneously in different places with no apparent connection with each other.

In tropical areas, especially sub-Sahara Africa, cases are most often seen during dry seasons, perhaps because changes in sleeping arrangements accompany the regression of the rainy season. In the dry season the dusty conditions drive workers indoors to sleep in crowded rooms.[80] In the cooler temperate zones, outbreaks tend to be clustered in the winter and spring months.[87] Recent data from Burkina Faso and Niger show annual peaks in the summer and fall.[88] In the United States, the peak incidence of meningococcal disease is in the late winter and early spring (February through May), and the lowest incidence is from July through October.

5.5. Age

Basically, meningitis is a childhood disease most often seen under age 15 years.[50,71,89] Beeson and Westerman,[90] in a study of 3,575 British cases, found that 45.5% occurred in children under 15 years. In the great Detroit epidemic,[91] children under 15 years made up 60% of the patients, while in the German epidemic of 1905–1907, 80% were under 15 years.[90] Recent US data confirm that the age-related predisposition of meningococcal meningitis still exists and that the peak incidence is from age 1 month to 1 year (Figure 3)

but that a lower peak is seen in late adolescence. The early peak in infancy is believed to be due to lack of protective antibody, while the peak for adolescents is believed to be due to exposure to carriers in crowds and in poorly ventilated locations such as bars and dormitories.

5.6. Sex

As is true of other severe diseases, males are more often subject to meningitis than females. In the Beeson and Westerman[90] study, the male–female ratio was 6:4, but fatalities were more frequent in females. The excess of males persisted through age 50 years. This preponderance was also noted in the Detroit civilian outbreak.[91] Since military forces in the past consisted predominantly of males, an excess prevalence of males is to be expected. Thus, in time of war, one should expect male cases to predominate, especially among recruits.

In a longitudinal study of meningococcal carriage in a population of "normal" families, it was found that males 20 years or older were more likely than adult females to become carriers.[76] However, recent data (2003) from the CDC show that 50% of cases of meningococcal disease occurred in males (annual rate in males = 0.60/100,000 and in females = 0.61/100,000[27]).

5.7. Race

Race seems to be of little significance for either the acquisition or the severity of infections, except that those with sickle-cell disease may be more prone to fatal infections, as they are to those caused by other polysaccharide-encapsulated bacteria. In a review of deaths from bacterial meningitis in the United States from 1962 to 1968,[92] it was concluded that excessive deaths from this cause were noted among African Americans and American Indians. Race per se is not mentioned as a risk factor, but poverty and crowding are. In a population-based study in Charleston County, South Carolina, neither race nor income affected the risk for meningococcal meningitis.[93] In the multistate surveillance study performed by the CDC in 1986, the rate of meningitis in African Americans caused by *N. meningitidis* was twice that of whites (1.5 vs 0.7/100,000), with Hispanics having a rate in between (1.1/100,000).[29] National data from the CDC for 2003 continue to show a higher annual incidence of meningococcal disease in African Americans (0.63/100,000) compared with whites (0.46/100,000). The rates for Asian Pacific Islanders (0.27/100,000) and for American Indians/Native Alaskans (0.26/100,000) are based on very small numbers. In terms of ethnicity, the rate for Hispanics (0.50/100,000) is higher than that for non-Hispanics (0.38/100,000).[27]

5.8. Occupation

Pike,[94] in an exhaustive review of laboratory-associated infections, records two such fatalities. In 1918, an employee of the State Serum Institute, Copenhagen, Denmark, whose job was concerned with the production of antimeningococcal serum, died of meningococcal meningitis. Another, an employee of the National Institutes of Health, in the United States, while injecting an animal with meningococci, had some of the syringe's contents sprayed into her eyes as the animal struggled. She became ill 4 days later and died after 4 days of illness.

The CDC reported two cases of fatal disease in 1988 in bacteriologists from California and Massachusetts who had handled meningococci in a laboratory, each having the

same isoenzyme type as a strain isolated from them at the time of their infection. There was considerable evidence of laboratory-acquired infection.[95]

While these cases indicate a potential occupational hazard, symptomatic infections with this organism are exceedingly rare. Nonetheless, it is prudent that laboratory personnel receive the tetravalent meningococcal polysaccharide or conjugate vaccine before taking up their work assignments and that laboratory workers who work with large quantities of organisms be protected with gloves and laboratory coats and use a class II biologic safety cabinet in a biosafety level 3 laboratory. Persons exposed to high-concentration aerosols or who have percutaneous exposures should have prophylaxis with treatment doses of penicillin.[7]

There are no other identifiable occupational hazards except for military recruits during periods of mobilization, who seem to have a special susceptibility that becomes manifest in outbreaks among them. A relatively high rate of meningococcal disease in college freshman living in dormitories suggests that age, crowding, and lifestyle may account for a peak of infection in military-aged individuals.

Despite great fears and expressed anxieties, physicians and nurses tend not to be excessively susceptible either to sporadic cases or during outbreaks. Arkwright[73] stated:

> It is almost universally accepted that doctors and hospital nurses seldom contract the disease. These and similar facts which have been observed in many epidemics are evidence against the spread of the disease being usually due to direct infection from one patient to another.

This concept has been modified in the present era by two new therapeutic procedures. Several cases of meningococcal disease have occurred among physicians who gave mouth-to-mouth resuscitation to patients severely affected by such infections. Feldman reported a case in which infection was apparently transferred with a kidney transplanted from an undiagnosed fatal case to a susceptible recipient.[96] Other than in the case of direct exposure to respiratory tract secretions of infected patients such as with mouth-to-mouth resuscitation, medical personnel do not require prophylaxis following the delivery of medical care to patients with meningococcal disease.

5.9. Occurrence in Different Settings

The most predictable outbreaks have been those that accompanied increased military mobilization and the induction of large numbers of recruits such as were noted in World Wars I and II and the Korean and Vietnamese mobilizations in the United States. The most extensive and largest outbreaks in the 20th century were those in civilians in sub-Saharan Africa and in Brazil. While more than a quarter of a million cases occurred in the latter, even under such conditions, outbreaks are spotty and concentrated in the poor and crowded;[54,70] e.g., during the Vietnamese mobilization, extensive outbreaks occurred among US Army and Navy recruits, while the Air Force and Marines experienced only sporadic cases and were spared the major epidemics that affected the other two services. One would assume that the induction system being what it is, susceptibles would have been distributed more or less equally among all four services. Cases were almost unknown among female recruits, but there were many fewer of them and their housing conditions were relatively uncrowded. Outbreaks of meningococcal disease in the military has not been a problem since the development of the polysaccharide meningococcal vaccine and its widespread use in the military throughout the world in the early 1970s.

Daniels et al.[97] reported that whereas a third of the troops at Fort Bragg, North Carolina, had less than 3 months of service, 59% of all patients with meningococcal infections were in this category. In other places, as many as 90% of cases were reported among recruits with less than 90 days of service. In the military, then, meningococcal infections represent a disease of recruits, whereas among seasoned troops or cadres in training, only sporadic cases are likely to be seen.[78] These are probably the result of deficiency of antibodies to specific circulating meningococcal strains.[98] A similar situation has been noted among South African miners, who represent a young population in whom meningococcal infections tend to occur early in their employment in the mines. Those who reenlist for a second tour of service are seldom troubled by this disease. Outbreaks may also be noted on occasion in institutions such as jails, mental asylums, residential schools, and other closed populations.

Outbreaks of meningococcal infection are quite uncommon in day-care centers or other infant-care facilities, but they have been reported, usually as part of a community outbreak. A report from the CDC, published in 1977,[99] described a cluster of three cases of serogroup B disease from a private home day-care center with nine attendees in Georgia. Review of the recent literature at that time revealed a cluster of three group B cases in a crowded church nursery attended by 40 children under 6 years of age in 1966–1967, and two group C cases in a day-care center in Dade County, Florida during an epidemic in 1969–1970.[99]

In 1981, there was a large outbreak of meningococcal disease in an elementary school classroom in Houston. In this outbreak there were five children and two siblings of one

child who became ill within a 6-day period with serogroup C *N. meningitidis*. This outbreak was unusual in that the children were 12 years old, older than in other reports of spread among children, and that disease was not noted in other classrooms or the community at large. Other studies of cases in school classrooms have been notable for the absence of secondary cases. Overcrowding may have been the major promoting spread of disease.[100]

In 1978 there was an outbreak of *N. meningitidis* serogroup A associated with the gathering at Medina and Mecca, Saudi Arabia, associated with the *Hajj* and more recently, in the years 2000–2001 there have been serious outbreaks of meningococcal disease (primarily serogroup W-135 but also serogroup A.[15–17,45]

5.10. Socioeconomic Factors

Outbreaks among civilians tend to occur among the poor, especially those who are overcrowded, ill-housed, and ill-fed.[70] In the great Brazilian epidemic of the 1970s, cases were concentrated in the barrios and typically were unusual among the middle and upper classes. Thus, even within cities, cases are often localized and confined to small areas rather than spread among the community as a whole. In a surveillance study of bacterial meningitis in Charleston County, South Carolina from 1961 to 1971, neither race nor income affected the risk of meningococcal meningitis, even though income was inversely correlated with rate of meningitis due to *Haemophilus influenzae* and *Streptococcus pneumoniae*.[93]

5.11. Other Factors

The principal factors that seem to be related to the occurrence of meningococcal infections are climatic conditions. In the sub-Sahara area, the change from the wet to the dry season tends to lead to an increase in cases. The reason for this relationship is unknown, although Belcher et al.[80] are of the opinion that considerably more population mixing takes place during the dry season, when farming work is reduced and more time is available for socializing and visiting. Also, there is a shift from sleeping outdoors to sleeping indoors in crowded and poorly ventilated rooms. In northern Ghana, the peak occurrence of cases comes during the dry season, when there is little rainfall, low humidity, and cold nights. Since this is the time when food becomes scarcer, it is popularly known as the "hunger season."

Familial and genetic factors may play a significant role in the acquisition of meningococcal disease. One example is that among those who lack one of the terminal complement components there is increased risk of infections due to neisserial species[101] (see Section 8.1.1).

6. Mechanisms and Routes of Transmission

Transmission of meningococcal infections is usually assumed to be by way of droplets from the respiratory tract, regardless of the clinical status of the individual. Organisms are present in almost pure culture in the posterior nasopharynx of colonized individuals. Direct transmission may occur during mouth-to-mouth resuscitation, by the transfer of infected blood, such as an accidental needle puncture from a contaminated syringe, or by organ transplant. Nosocomial transmission, while probably very rare, was documented by Cohen et al.[102] in New Haven, Connecticut. At a time when two patients in a cancer ward developed group Y meningococcal infections, the prevalence of asymptomatic pharyngeal carriage of group Y strains was 10% among other patients on the ward. The carriage prevalence was significantly lower in ward workers and casual visitors. Spread was presumably due to airborne transmission.

Acute, purulent meningococcal urethritis[103] has been reported along with reports of isolations of meningococci from the cervix[104,105] and other unusual areas.[106–114] How often these reflect sexual activity or generalized infection is unclear. It has been suggested that cervical acquisitions may be related to orogenital sex, or perhaps transmitted by a male with meningococcal urethritis, or the result of generalized dissemination during mild meningococcemia. Whether direct cervical implantation leads to clinical systemic disease is unknown.

6.1. Secondary Attack Rate

Considerable confusion has surrounded the calculation and interpretation of secondary attack rates of meningococcal disease. Norton,[115] in his study of the meningococcal epidemic of 1929 in Detroit, found among the 724 cases of meningitis, 32 (4.4%) additional cases in households. Among these additional cases, he believed that 2 could be eliminated completely, leading to the conclusion that there had been 30 secondary household cases. In the Santiago, Chile epidemic, Pizzi[70] calculated the secondary attack rate to be 3.9% for those less than 15 years of age and 1.5% for those older than 15. For all ages during this epidemic of 5,885 cases, the secondary attack rate was 2.5%. During the massive Brazilian epidemic, a study[116] conducted among classmates of children who had meningococcal disease was

interpreted as indicating that classroom exposure to cases did not increase the risk of acquiring meningococcal meningitis. The authors concluded that such exposure was an insufficient indication for prophylactic chemotherapy.

The Meningococcal Disease Surveillance Group,[117] organized by the CDC, analyzed 326 cases reported in the United States from November 1973 through March 1974. Three household members manifested meningococcal disease following initial cases in their homes, a secondary attack rate of approximately 3/1,000 household members at risk. Among 293 households for whom follow-up data were available, 4 had two cases and none had more than two. In this study, cases in contacts with onset within 24 h of the case to which they were exposed were labeled "co-primary." In 107 households in which no chemoprophylaxis was administered to any household members, the secondary attack rate was 2.2/1,000. The authors concluded that a secondary attack rate of 2–4/1,000 is still a thousand times greater than the overall reported rate of 0.23/100,000 of meningococcal disease in the states in which the cases were studied.

Clearly data on secondary attack rates during nonepidemic periods estimate lower rates than in earlier studies which were performed during outbreaks. A recent review by Purcell et al.[118] looked at studies performed since the early 1970s that calculated the attack rate for household contacts who did or did not receive antibiotic prophylaxis. The attack rates varied from 0 to 5/1,000.

It is not always clear whether a distinction is drawn between secondary and co-primary cases, as was attempted by Leedom et al.[119] in a 3-year study of Los Angeles County cases. There were 290 different families, 3.4% of which had more than one case. From a sample of these cases, it was determined that the average number of people residing in the same household with each patient was 3.71. The risk of multiple cases among household contacts of patients was estimated to be 992/100,000. The 3-year case average (1963–1965) for Los Angeles County was 2.09/100,000. One household had three cases. The onset of disease was basically simultaneous among all family members except for three in which the cases were separated by 5, 7, and 9 days. The remainder, then, would be considered to have been co-primary cases. The high rate of secondary cases during epidemics compared with the rate with endemic disease may be due to multiple factors, but the problem of assigning status as a true secondary case may be more difficult during an epidemic.

What, then, are the implications of using these different designations, or is it solely a matter of semantics? The incubation period for meningococcal disease varies from 2 to 10 days, commonly 3–4 days.[120] Bolduan and Goodwin,[121] in a 1905 study in New York City, identified 88 instances where there was more than one case in a house. Among 58 of these, the interval between the index and the second case was 7 days in 14 and 2 weeks to 3 months in 16. Norton[115] stated that among 6,416 household contacts of 1,272 cases, there were 36 homes with more than one case. In three, two persons became ill the same day, and in another, there were four simultaneous onsets. The latter had a fifth case sometime later. Norton calculated that while 3.6% of homes had additional cases after their first, there were 46 (0.7%) secondary cases among 6,416 contacts. Of these 46, 20 had their onsets within 4 days and 14 within the next 5 days, or 34 (74%) within 9 days of the index patient. Thus, with an incubation period up to 10 days, most of these "secondary" cases may be really co-primary. In contrast, Jacobson et al.[116] defined a secondary case as "the onset of illness more than 24 h and less than 31 days after onset of another case in the same classroom." Their definition was more applicable to the issue of prophylaxis where it is unlikely that an oral prophylactic agent would affect an already-invasive infection.

7. Pathogenesis and Immunity

Meningococci are generally transmitted via droplets or through close oral contact. The organisms have a predilection for the posterior nasopharynx and can often be obtained in almost pure culture from that area. It was believed for a long time that the bacteria penetrated to the central nervous system through the cribriform plate, but there is no real evidence for this. Dingle and Finland[87] summarized the evidence for and against this concept and decided, as had most observers, that dissemination from the posterior nasopharynx is via the bloodstream. Once the bloodstream has been entered, a variety of consequences may follow, leading to various clinical expressions.[81] As shown in Table 1, these manifestations may run the gamut from mild, self-limited bacteremia—which may or may not be accompanied by low-grade fever, a pinkish, maculopapular rash, arthralgias with malaise, and muscle pains—to overwhelming sepsis with a coalescing, extensive petechial rash that may lead to large areas of necrosis. Disseminated intravascular coagulation, meningitis, septic arthritis, epididymitis, myocarditis, conjunctivitis, adrenal collapse (Waterhouse–Friderichsen syndrome), and death within an hour or two may follow. Fortunately, it is only the rare individual who falls into this latter category. What there is about such individuals that makes them especially susceptible to such severe disease manifestations is unknown, but they arouse the greatest interest and serve to direct attention to the disease. Probably as many as 90% of those who acquire meningococci have infections that are limited to the posterior

nasopharynx with, occasionally perhaps, self-limited bacteremia. Whether infection limited to the posterior nasopharynx leads to clinical signs has been debated for decades and remains unresolved. Unfortunately, most such studies have been performed among military recruits, who are notorious for the amount of bacterial, mycoplasmal, and viral upper-respiratory infections that they support. Each of these agents would have to be excluded before one could conclude that meningococci are producing the reference symptoms. It is the prevalence of posterior nasopharyngeal infections and the paucity of clinical disease that complicate our understanding of the epidemiology of these diseases. That relationship led Arkwright[73] to conclude that epidemics basically affect the nasopharynx and that cases of meningitis and other complications are incidental. This also explains the apparent indiscriminate occurrence of clinical disease and the lack of evidence for direct connections between cases.

Immunity has been studied extensively during the past three decades. Serum antibodies have been demonstrated by a variety of techniques, including radioimmunoassay,[122] bactericidal,[98,123] hemagglutination,[124] agglutination,[123,125] and others. The solid-phase radioimmunoassay is particularly suited to determination of antibody to noncapsular antigens.[126] Immunity is acquired as the result of infection even when this seems to have been limited to the posterior nasopharynx.[123,127] Thus, the carrier state can induce immunity to the serogroup of the organism carried. The presence of bactericidal antibodies correlates well with protection from disease.[98,127] Bactericidal antibody assays are still used for measuring protection in vaccine trials. Because the endemic meningococcal disease rate is so low, vaccine efficacy trials are still reported as inducing a titer of bactericidal antibody and not reduction of disease. The presence of bactericidal antibody to serogroups not in circulation in specific populations suggests the importance of antibody to protein and LOS type-specific antigens that are shared among serogroups.

An alternative hypothesis for the role of antibody, in military recruits, was proposed by Griffiss.[128] He has found antimeningococcal IgA in the acute sera of military recruits who had meningococcal disease. This IgA was able to inhibit the lytic function IgM in sera. Removal of IgA made sera that appeared to lack bactericidal antibody functionally lytic. Thus, it was Griffiss' contention that susceptibility, in addition to being defined by the *absence* of functional antibody, may be due, in some cases, to the *presence* of blocking IgA.[128] Thus, as it is the acquisition of new strains of meningococci that represents the major risk factor for invasive disease, true susceptibility may also be related to exposure to successive waves of meningococci. The role of this mechanism, if any, in civilian endemic disease is unknown.

8. Patterns of Host Response

Inapparent infections play an important role in meningococcal disease because they constitute the majority and account for the bulk of carriers. As has been noted, the acquisition of the carrier state leads to immunity,[98,123] and thus protection against the disease itself. We have no information as to why, among children, an occasional individual is unable to restrict the acquired meningococci to the posterior nasopharynx and becomes the victim of a life-threatening disease episode. Among adults, deficiency of lytic antibody appears to be the major predisposing factor accounting for biological susceptibility to meningococcal disease. The reason why a small number of adults lack antibody is also unknown. Either they were never colonized or colonization did not result in the production of a long-lasting antibody response.

8.1. Clinical Features

Meningococcal infections may manifest themselves clinically by several different syndromes (see Table 1). These may overlap or be noted sequentially in the same patient. The most common occurrence is represented by the asymptomatic acquisition of meningococci in the posterior nasopharynx or the carrier state. While there are some who believe that an acute pharyngitis may be clinically manifest in this stage, this has never really been proven. Thus, disease is probably limited to less than 10% of those who acquire meningococci. The next stage may be that of a mild, self-limited bacteremia that may be accompanied by an evanescent rubella-like rash, arthralgias, fever, malaise, and myalgias. A blood culture taken at this time is often positive for meningococci. This may regress completely or for several days, only to be followed by an explosive onset of severe illness. This is generally heralded or accompanied by a severe petechial rash that may be very extensive and coalescent, with large areas of necrotic skin and muscle. Similar lesions probably occur in the deeper viscera.

Prostration and shock may follow in short order, with death close behind. Smears made from petechial lesions or from the buffy coat of peripheral blood may contain gram-negative diplococci within or outside of cells. This is the most devastating form of the infection, in which septicemia is so severe and overwhelming that often the patient dies before there is localization in the CNS, joints, or other organs.

A less virulent form of septicemia is more common, and while this too is identifiable with a petechial rash, progression is slower and permits other complications to become evident. These patients often are the cases with meningitis, septic arthritis, epididymitis, pneumonitis with pneumonia, conjunctivitis, and myocarditis. All these may occur in a single patient or in any combination thereof.

In infants, "mild" meningococcemia may present with fever as the only symptom. This presentation of meningococcemia is very similar to that of occult pneumonococcemia, which occurs more frequently than meningococcemia in ambulatory pediatric patients.[129,130] So far it has not been possible to differentiate children with meningococcemia who are in the early stages of infection and are destined to develop fulminant disease from those who will clear the infection on their own. A retrospective study to determine whether any hematological parameters differentiated febrile pediatric patients with unsuspected meningococcemia from those with sterile blood cultures only found that the percentage of band forms was higher in those with unsuspected meningococcemia. However, the predictive value of an elevated band count was too low to be of practical value.[131]

Discrete meningococcal pneumonia has also been reported, especially from the military. Group Y meningococcus has often been implicated in this form of infection.[112] Koppes et al.[132] reported on 88 cases of group Y meningococcal disease in Air Force recruits, 68 of whom had primary bacterial pneumonia. All but one did well with penicillin therapy. It is possible that the predominance of group Y in these cases reflected immunization with group C polysaccharide vaccine, which had been instituted as a routine procedure in the Air Force. In this study, 52 of 64 individuals sampled had pure cultures of group Y meningococci in transtracheal aspirates. In the remainder, growth was due primarily to group Y meningococci, with relatively small amounts of contaminants such as α-streptococci, *Haemophilus influenzae* type b, and others. Primary meningococcal pneumonia, either alone or in concert with other evidence of septic meningococcal infections, has been reported often enough to constitute a disease entity, establishment of the identity of which should be sought in cases of otherwise undefined pneumonia.

Group Y meningococcal infections have also occurred in children.[129,133,134] Pneumonia was reported in one case.[134] Group W-135, which has increased in incidence in the past two decades, has also been reported to have a varied presentation in children, similar to other serogroups.[14,135]

There is an unusual and infrequently seen form of the disease that is identified as chronic meningococcemia. This may be a manifestation of subacute bacterial endocarditis or the result of continuous seeding into the bloodstream from an unknown nidus. Such patients may go for weeks or months with recurring fever and evanescent rashes, as either pink macules or small petechiae. Arthritis has frequently been reported with chronic meningococcemia. They respond rapidly to treatment and are often cured by penicillin administered for other reasons, such as a suspected infectious cause of the fever, malaise, and rash.

8.1.1. Genetic Determinants of Meningococcal Disease: Complement Deficiency. Petersen et al.[101] summarized information from various reports of 24 patients who had had recurrent episodes of meningococcal or (generalized) gonorrheal infections. Their distinguishing characteristic is that they lacked one or more of the late components of the complement system: C6, C7, or C8. Of the 24 patients, 6 were deficient in either C6 or C7 and 8 in C8. In all, 13 of the 24 had either *N. meningitidis* or *N. gonorrhoeae* bacteremia, and all recovered. The patient with C7 deficiency apparently recovered from four episodes of meningococcal meningitis. The frequency of this abnormality is unknown, but it would seem that while the propensity to have recurrent neisserial infections is present in such individuals, the disease does not appear to be overwhelming or fatal, since so many seem to have recovered. From subsequent reports it appears that deficiency of C5 and C9 are also risk factors for neisserial infections.

Ellison et al.[136] studied 20 adults with a first episode of meningococcal infection. Six of them had a complement deficiency. Of these six, three had a specific terminal component deficiency and three had multiple component deficiencies due to an underlying illness. In children, the prevalence of underlying complement deficiency in those with one meningococcal infection was 18% in one study.[137] In a larger study, of 544 patients with meningitis or bacteremia due to encapsulated organisms, seven had complement deficiencies; of those seven, six experienced meningococcal infection and one had pneumococcal bacteremia.[138] While the rate of complement deficiencies varies between ethnic groups, the estimate of prevalence is 0.03%. The prevalence of patients with complement deficiencies among those with meningococcal infections is higher when the case is sporadic, in an area of low incidence, than when it is part of a meningococcal outbreak. In a study comparing complement-sufficient patients who had meningococcal disease with patients with complement defects, those with complement defects were older (mean age of 17 years vs. 3 years), more likely to have recurrence and relapse, and had a much lower mortality rate (1.5 vs. 19%).[138] In a recent review Emonts et al.[139] list a number of genetic polymorphisms in the classical complement pathway and in the properdin

innate immunity pathways that increase the risk for invasive meningococcal infections. Immunization with meningococcal polysaccharide vaccine appears to offer some individuals with complement deficiencies protection from meningococcal disease.[140]

Corfield[141] may have recorded the first such case in 1945 and suggests another, seen by Boudin, in whom three episodes occurred in 1849, 1850, and 1851. These cases are to be separated from the recurrent disease that was encountered before modern therapy prevented the frequent bacterial relapses common to that era. Patients who have recurrent disseminated neisserial disease should be screened with CH_{50} assays, and if they are positive, specific deficiencies should be sought.

8.1.2. Other Genetic Determinants of Meningococcal Disease. Recent publications suggest susceptibility to meningococcal disease may be related to mutations and variations in genes controlling toll-like receptors. Smirnova et al.[142] reported that TLR4 variants were over-represented in the population of patients with meningococcal sepsis, while other toll-like receptors appeared to be normal. Other genetic polymorphisms associated with decreased bactericidal capacity with increased susceptibility to meningococcal infections include variants of FCγ receptors, polymorphisms in the tumor necrosis factor$_\alpha$ (TNF$_\alpha$) promoter, and variants in other cytokines including in the interleukin family.[139]

8.2. Diagnosis

As is true of many diseases, the frequency of the diagnosis of meningitis often reflects the observer's index of suspicion. The carrier state is not diagnosable except by culture and is of little importance except under some very special circumstances. In the case of invasive disease, diagnosis generally requires laboratory confirmation. With this in mind, blood cultures should be obtained as quickly as possible. If there are clinical signs of meningitis, an immediate lumbar puncture is mandatory, followed by prompt examination of the fluid. Its cellular content should be ascertained as to type and number. Sugar and protein should be measured (one should determine the comparative blood sugar at the same time.). A Gram's stain should be performed on a smear made from the fluid if the fluid is cloudy; but if it is clear, a concentrated specimen should be made after centrifugation. Fluid should be cultured on chocolate agar in an atmosphere of increased CO_2. While rarely performed today because of the lack of laboratory space on treatment units Gram's stains of smears of fluid from petechial lesions or buffy coats of peripheral blood may also yield gram-negative diplococci. If these are present, then they are most likely meningococci. The peripheral white blood count is usually elevated, but in severely ill patients, it may be less than 4,000/mm^3. If a patient has been treated with antibiotics prior to obtaining samples for culture detection of antigens in blood, urine, or spinal fluid using the latex agglutination test may be helpful in making a diagnosis even if the cultures are sterile. Lack of demand for this test has resulted in its removal from many clinical laboratories. Employment of broad-spectrum antibiotics has reduced the need to make a "bedside" specification.

Because of the nature of the rash and the clinically severe illness, the diagnosis may be confused with Rocky Mountain spotted fever. Less severe cases may be confused with endemic typhus and, when very mild, even with rubella.

9. Control and Prevention

9.1. General Concepts

Because cases of meningococcal disease tend to be distributed indiscriminately in a population and because death may be sudden, the appearance of a case frequently leads to generalized hysteria in the associated population, whether it be open or closed. Outbreaks tend to occur in closed groups such as institutions, recruit military camps, and crowded, impoverished districts of major cities.[6,70] As with poliomyelitis, cases rarely lead to other cases, an observation that understandably tends to increase fear and hysteria among the populace in which the cases occur.

Sporadic cases of meningococcal disease occur throughout the year in all places. They often appear as isolated instances for reasons that are not understood. Close contacts of individuals with meningococcal disease have higher carriage rates than the general population and secondary cases of invasive disease account for 1–3% of all meningococcal cases.[40,143] More incomprehensibly, cases may begin to occur in rapid succession in a given population. These are usually closed, institutionalized settings, but numerous cases may be noted in the community at large and constitute an epidemic.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis: Suggestions for the Management of Outbreaks

Before rational intervention can be instituted or attempted when it is suspected that cases of meningococcal disease significantly above the endemic rate are occurring, two important questions must be answered. First, can the affected population be defined; and second, what are the characteristics of the causative agent? In respect to the latter, is it of a single serogroup?

Once appropriate antibiotic prophylaxis is given in a large population the carrier rate may be expected to drop to near zero almost immediately, slowly rebuilding itself over a period of weeks. Cases also stop occurring as the carrier rate diminishes. It is required, for maximum benefit, that prophylactic treatment be simultaneous for the total target population. In the past sulfonamides were the first-choice antibiotics for prophylaxis but in much of the world sulfonamide resistance of meningococci has led to the use of alternative antibiotics (Table 2).

Another option is to attempt to immunize the population with a polysaccharide or conjugate meningococcal vaccine. The latter is feasible only if the causative organisms are of serogroups A, C, Y, or W-135. The licensed vaccines contain the polysaccharides of groups A, C, Y, and W-135, and only a single dose is required. When the vaccine is used, it must be anticipated that maximum beneficial effects will be noted after 10–14 days, although diminution in the severity of the disease in some cases may be observed by the 7th day.

Of the other chemoprophylacticagents rifampin is most often used. The dose of rifampin is listed in Table 2. Minocycline, recommended in the past, is rarely used for this indication because of gastrointestinal and vestibular toxicity.[53,54] Resistance to rifampin has been noted in as many as one fourth of strains. This proportion increased with repeated courses of the drug in the same population. A single intramuscular dose of ceftriaxone is effective in eradicating meningococci from the pharynx,[144,145] and it can be used for meningococcal prophylaxis. Its high cost and difficulty of administration limit the usefulness of this option to special circumstances where repeated oral dosing is not practical. Ciprofloxacin is approved for this use as a single dose but resistance has been reported in Europe and Asia but is rare in the U.S. It should not be used in locales where resistance has been reported.

9.3. Immunization

Gotschlich, Goldschneider, Artenstein, and their colleagues,[98,124,127] in the search for an effective alternative to sulfonamide prevention of meningococcal disease, successfully reopened the investigation of vaccines, an approach that had lain dormant for a quarter of a century. A series of publications beginning with the demonstration of the importance of serum antibodies in protection against the disease,[98] the effectiveness of pure carbohydrate antigens[124,127] in stimulating specific immunity against infection with organisms of the various serogroups, and finally the value of such antigenic stimulation in providing protection against the disease during epidemic periods[26] was probably the most important contribution to the meningococcal problem in the twentieth century. Subsequently, group A meningococcal vaccine was used in the management of large epidemics of disease in Finland,[7] Brazil,[6] and Egypt.[146] Effective polysaccharide immunogens for groups Y and W135 appeared later.[147]

Greenwood et al.[148] evaluated the effectiveness of group A vaccine in preventing secondary cases when administered to household contacts of group A cases and found the secondary attack rate to be 18/1,000 among control household contacts who received tetanus toxoid. Among the 520 case contacts who had received group A meningococcal vaccine, there was only one instance of meningococcal disease. The efficacy of the group A meningococcal vaccine was clearly demonstrated in the trial of Peltola et al.[25] in Finland in 1974–1975. In two trials conducted during an epidemic of group A meningococcal disease, 49,295 and 21,007 children, aged 3 months to 5 years, received the vaccine. None developed group A meningococcal disease. In the first trial there were two control groups that had significantly more cases than the vaccine group.

Despite the Finnish experience, there is good evidence that in children the degree of antibody response to the groups A and C vaccine, measured as the concentration of anticapsular antibody in the serum, is proportional to age. Children under 1 year of age have a poor response and no immunologic memory.[149,150] As is seen for other polysaccharide vaccines that are non-T-cell-dependent immunogens, it is not until 2 years of age that there is sufficient maturation of the immune system for there to be a protective antibody response to group C polysaccharide, although the response to the group A polysaccharide appears to occur earlier.[149,150]

Initially, meningococcal vaccine was marketed for civilian use as 50 μg of group A polysaccharide, 50 μg of group C polysaccharide, or a combination of both. In 1981, a tetravalent vaccine consisting of 50 μg each of groups A, C, Y, and W-135 capsular polysaccharides was shown to be safe and immunogenic and has been licensed (Menomune, currently manufactured by Sanofi-Pasteur, Inc.).[151] A single 0.5-ml dose of vaccine is sufficient to immunize a child over 2 years of age or an adult. Adverse reactions have not presented a problem, generally being limited to local erythema or soreness or both, usually persisting for not more than 24 h.[152] After group B, the commonest, these four are the most common groups causing meningococcal disease in the United States. Despite extensive research into production of a nonpolysaccharide vaccine or a polysaccharide conjugated with another immunogen, there is no commercially available group B vaccine at this time.

An improved meningococcal vaccine was developed using methods proven to be successful with conjugate polysaccharide vaccines for *Streptococcus pneumoniae*

and *Haemophilus influenzae*. As is true of these species, *N. meningitidis* capsular polysaccharides are T-cell-independent antigens and immunization does not elicit a memory response. This results in inducing a response that is neither long lasting nor characterized by anamnestic response after subsequent challenge with the same polysaccharide antigen. Thus meningococcal polysaccharide vaccines do not confer long-lasting immunity. Covalent coupling of polysaccharide to a protein carrier results in a conjugate vaccine and this changes the expression of the immune response to the polysaccharide from T-cell independent to T-cell dependent, resulting in an improved primary response to the polysaccharide and a strong anamnestic response with re-exposure. Proof that this method of vaccine design results in a potent infant vaccine has come from the experience with vaccines for *H. influenzae* type b and *S. pneumoniae*. Both conjugate *H influenzae* type b and conjugate *S pneumoniae* vaccines which were introduced for mass infant immunization in the United States in 1990 and 2000, respectively, and have been successful in reducing the incidence of disease caused by serotypes contained in the vaccines.[153,154] An added benefit of these conjugate vaccines is that they decrease the rate of nasopharyngeal colonization of the respective bacteria, thus providing unimmunized individuals protection through a herd-immunity effect. Conjugate meningococcal vaccine was introduced in the United Kingdom in 1999. With only immunogenicity and safety data three 3 monovalent serogroup C conjugate vaccines were introduced. Infants were given a 3-dose immunization series targeting all children between 12 months and 17 years of age. By 2001–2002, vaccine coverage in the United Kingdom was estimated at 80% in infants, 84% in toddlers, 76% in preschoolers, and 87% in school-aged children. Effectiveness of the meningococcal group C conjugate vaccines within the first year of immunization ranged from 88 to 98% in different age groups. Duration of the protective response is unknown.[40]

In the United States a quadrivalent conjugate meningococcal vaccine (Menactra, produced by Sanofi-Pasteur, Inc) was approved for individuals from 11 to 55 years of age in January 2005. Menactra contains the capsular polysaccharides from serogroups A, C, Y, and W-135 (4 μg each) conjugated to 48 μg of diphtheria toxoid (Tables 3 and 4). It is expected to provide longer-lasting protection from meningococcal disease than Menomune and may also be better at preventing the spread of disease from person-to-person. Protective concentrations of antibodies are achieved within 8 days of immunization. Both vaccines induce protective antibodies against serogroups in the vaccine in more than 90% of those who get the vaccine. Both prevent meningococcal disease due to serogroups A, C, Y, and W-135 but neither prevents disease due to meningococcal serogroup B.

For the polysaccharide vaccine antibody responses have been found to persist for at least 5 years.[155] There is insufficient data to recommend a revaccination schedule for the conjugate vaccine at this time.

9.3.1. Application. Before the development of the conjugated meningococcal vaccine the incidence of meningococcal disease in the US general population had been considered to be too low to warrant wide-scale immunization with the available meningococcal vaccines. In the United States, group A meningococcal infections have been very rare since the end of World War II, while groups B and C have provided most of the interim cases. In recent decades groups Y and W-135 have emerged as common where previously they had been rare.

On the other hand, the 4-year Brazilian epidemic[6] of the 1970s resulted in more than a quarter of a million cases. In the first 2 years, this was essentially a group C epidemic that then became a group A epidemic. A massive countrywide immunization campaign was undertaken, which eventually meant that more than 80 million persons received bivalent A and C, or monovalent A or C, vaccines. This

Table 3. Meningococcal Vaccines Available in the United States (2005)

Generic Name of Vaccines	Meningococcal conjugate vaccine	Meningococcal polysaccharide vaccine
Brand Name of Vaccine	Menactra	Menomune
Manufacturer	Sanofi Pasteur Inc.	Sanofi Pasteur Inc.
Year of Licensure	January 2005	1981
Recommended age of vaccines	2–55 years	> 2 years
Schedule of vaccination and route	Single dose, intramuscularly	Single dose, subcutaneously
Serogroups covered	A, C, Y, W-135	A, C, Y, W-135
Chemistry	Capsular polysaccharide linked to protein (diphtheria toxoid)	Capsular polysaccharide
Length of protection	Unknown	Excellent 3–5 years

Source: Meningococcal Disease and Meningococcal Vaccines April 2005. CDC, accessed at http://www.cdc.gov/nip/vaccine/mening/mening_fs.htm

Table 4. Meningococcal Vaccine is Recommended for:

- All children 11–12-year-olds at their routine preadolescent check-up
- If not previously vaccinated, adolescents should be vaccinated before they enter high school, at around 15 years of age
- People who have an elevated risk of meningococcal disease including:
  - ☐ College freshmen living in dormitories
  - ☐ Microbiologists who are routinely exposed to isolates of *N. meningitidis*
  - ☐ Military recruits
  - ☐ People who travel to, or live in countries where meningococcal disease is very common.
  - ☐ Anyone greater than 2 years of age whose spleen has been damaged or removed and persons with certain other immune system disorders.
  - ☐ Persons advised to receive vaccination during an outbreak

The following should not receive meningococcal conjugate vaccine:

- Anyone who has ever had a severe (life-threatening) allergic reaction to a previous dose of either meningococcal vaccine should not get another dose.
- Anyone who has a severe (life-threatening) allergy to any vaccine component should not get the vaccine.
- Anyone who is moderately or severely ill at the time the shot is scheduled should probably wait until they recover. People with a mild illness can usually get the vaccine.
- Anyone who has had Guillien Barré syndrome.
- Meningococcal vaccines may be given to pregnant women. However, MCV-4 is a new vaccine and has not been studied in pregnant women as much as MPSV-4 has.

brought the epidemic to a close and it did not recur. In Finland, a large outbreak in the military, accompanied by many civilian cases, was also treated with vaccine and was soon brought under control.[7]

As a result of the successes of the conjugate polysaccharide vaccines for *H. influenzae* and *S. pneumoniae* and recognition of the relatively high risk of older adolescents for meningococcal infection, recommendations for meningococcal vaccine have recently been revised.[156] Table 4 shows the current recommendation for meningococcal vaccine. Menactra is recommended as the preferred vaccine for those 2–55 years of age. For others greater than 2 years old, Menomune is recommended. Vaccination is indicated where localized or institutional outbreaks can be defined and the causative strain identified as either group A, C, Y, or W-135. A guideline has been provided by the Centers for Disease Control and Prevention. Meningococcal vaccine can be considered for general use in a defined population at risk if there are three or more primary cases with the same serogroup and the serogroup-specific rate of meningococcal infection in a defined population exceeds 10 times the baseline or expected rate for that serogroup over a 3-month period. (generally $\geq$10/100,000 population) Usage to prevent secondary cases among close contacts is recommended by the CDC,[157] but the overall risk is low and most such cases occur within less than 6 or at most 9–10 days of the index case. Thus, chemotherapeutic measures should be more effective.

In addition, patients with functional or anatomic asplenia, such as in sickle-cell disease or traumatic rupture of the spleen, are prone to severe or fatal infections with polysaccharide-encapsulated bacteria. Individuals with deficiencies of the terminal complement components may also have recurrent meningococcal infections. Patients over 2 years of age who fit any of these categories should receive the current meningococcal vaccine as part of their preventive care. While younger patients might have benefit from the serogroup A component, the risk of group A disease is too low to warrant vaccine in most Western countries.

Meningococcal vaccine is also recommended for travelers to countries known to have an epidemic of meningococcal disease or where the endemic rate is very high such as sub-Saharan Africa or in certain regions of Saudi Arabia at the time of the *Hajj*.

10. Unresolved Problems

The greatest unresolved problems are the elucidation of the factors that lead to the occurrence of a case; i.e., of the many individuals who acquire meningococci carriage, why do only so few (probably less than 10%) develop meningococcal disease? In parallel with this is the question of which factor or factors lead to the occurrence of an epidemic in a given locality or institution. Such epidemics arise suddenly and for no apparent reason persist for varying periods of time—days, weeks, months, or years—and then either disappear completely or are replaced by meningococci of another serogroup. Are the factors responsible for these fluxes changes in the pathogen, the host or a combination of the two?

Questions remain concerning the use of the current meningococcal vaccines. This involves questions of optimal timing and the definition of the population that would benefit most from their use, as well as the definition of the conditions under which they achieve maximum effectiveness. There are few data that address the question of revaccination. We still lack vaccines for children under 2 years of age that will protect against the major serogroups. The new conjugate meningococcal vaccine may be useful for these children but only limited studies in infants and young children are available. We still lack an effective vaccine for group B *N. meningitidis*.

CHAPTER 25

Mycoplasma pneumoniae and Other Human Mycoplasmas

Deborah F. Talkington and Ken B. Waites

1. Introduction

Mycoplasmas are a class of fascinating wall-less bacteria that cause disease in humans, animals, and plants. They include species recognized as among the smallest known free-living cells. These microbes have very small genomes and unique genetic features. Their temporary classification as viruses and fastidious growth requirements set the stage early for the use of diagnostic techniques better suited to viral detection and for the well-known difficulties of diagnosing infections in the clinical laboratory. Systemic infections are well known in both immunocompetent and immunocompromised patients, but the host and bacterial factors that allow invasion from epithelial colonization sites are poorly understood. The focus of this chapter will be respiratory and extrapulmonary infections caused by *Mycoplasma pneumoniae* and genitourinary tract infections caused by *M. hominis*, *M. genitalium*, and *Ureaplasma* species. Some less common mycoplasma infections will also be addressed.

2. Historical Background

In 1898, Nocard and Roux reported the first culture isolation of a mycoplasma, the bovine pleuropneumonia agent now known as *M. mycoides* subsp. mycoides.[1] Evidence gradually accumulated that mycoplasmas had a role in various diseases of animals and possibly in human disease. Klieneberger introduced the concept in the 1930s that mycoplasmas were "L forms" of bacteria lacking cell walls and living symbiotically with other walled bacteria.[2] This theory started a spirited debate pitting those who believed that mycoplasmas were unique species against those who believed that mycoplasmas were wall-less variants of other known bacterial species and were undeserving of a unique taxonomic representation (this controversy was not completely settled until the 1960s when DNA analysis showed that mycoplasmas were indeed unique bacteria that lacked the ability to produce cell walls under any circumstances). Dienes and Edsall are commonly credited with the first mycoplasma isolation from humans in 1937 when they reported what is believed to be *M. hominis* in culture from a Bartholin gland abscess.[3–6]

In 1944, Eaton succeeded in isolating a "filterable" agent from the sputum of a patient with primary atypical pneumonia using tissue culture.[7] Tests on volunteers and field studies conducted in the 1950s and 1960s provided definitive evidence that the "Eaton agent" caused lower respiratory tract infections in humans.[8,9] The Eaton agent was considered to be a virus until it became clear that antibiotics could be effective against it, and in 1961 Marmion and Goodburn postulated that the Eaton agent was a PPLO.[10] Culture in cell-free medium was achieved and in 1963 the taxonomic designation *M. pneumoniae* was proposed.[11]

The term "mycoplasma" (Greek; "mykes" = fungus and plasma = "formed") emerged in the late 1950s as a less linguistically challenging replacement for the term "pleuropneumonia-like organisms," or "PPLO." The allusion

Table 1. Selected Mycoplasmas Cultured from Humans[a]

Organism	Primary Site of Colonization		Known Disease Role in Immunocompetent People?
	Respiratory Tract	Genitourinary Tract	
Acholeplasma laidlawii	+	–	No
Mycoplasma buccale	+	–	No
Mycoplasma faucium	+	–	No
Mycoplasma fermentans	+	+	Yes?
Mycoplasma hominis	–	+	Yes
Mycoplasma genitalium	–	+	Yes
Mycoplasma lipophilum	+	–	No
Mycoplasma orale	+	–	No
Mycoplasma pirum	?	?	No
Mycoplasma penetrans	–	+	?
Mycoplasma primatum	+	+	No
Mycoplasma salivarium	+	–	No
Mycoplasma pneumoniae	+	–	Yes
Mycoplasma spermatophilum	–	+	No
Ureaplasma urealyticum	–	+	Yes
Ureaplasma parvum	–	+	Yes
Mycoplasma amphoriforme	+	?	?

[a]Adapted from[5]

to a fungus-like growth pattern in the name happens to describe only the growth of *M. mycoides*, but the term was nevertheless adopted. As the single order of mycoplasmas grew to three orders by the late 1960s, mycoplasmas were elevated to a class named Mollicutes, which derives from Latin words meaning soft ("mollis") and skin ("cutis"). The term Mollicutes is now used in general to refer to the current four orders.[4,6]

Of more than 150 mycoplasma species identified, fewer than 20 are known to colonize or infect immunocompetent humans, with most showing a predilection for either the respiratory or urogenital tracts in normal individuals (Table 1).

3. Methodology

3.1. Clinical Diagnosis

The clinical presentation of *M. pneumoniae* respiratory disease is similar to that seen with other atypical bacterial pathogens such as *Chlamydophila pneumoniae* and legionellae and in some cases infections with *Streptococcus pneumoniae* and various respiratory viruses and rickettsiae. *M. pneumoniae* may be present in the respiratory tract concomitantly with other pathogens,[12,13] and a chronic carrier state may be apparent in the absence of overt disease.[14]

The radiographic findings in mycoplasmal pneumonia can be extremely variable and mimic a wide variety of lung diseases, but sometimes the radiologic appearance coupled with clinical manifestations give clues to a mycoplasmal etiology. The inflammatory response elicited by *M. pneumoniae* causes interstitial mononuclear inflammation in the lungs that may be manifested radiographically as bronchopneumonia of the perihilar regions or lower lobes, usually with a unilateral distribution, and hilar adenopathy. However, lobar consolidation has been described, and the degree of consolidation may exceed what would be expected based on the severity of clinical manifestations. Among patients with mycoplasma pneumonia who require hospitalization, over 10% will require mechanical ventilation.[15] Pleural effusions and diffuse alveolar damage sometimes occur in association with more severe cases,[16–18] and long-term sequelae such as bronchiectasis and pulmonary fibrosis have been reported.[19,20] In some patients, the organism may persist for weeks to months in the lower respiratory tract following acute pneumonia, resulting in prolonged reduced pulmonary clearance and airway hyper-responsiveness.[21] Mycoplasmal pneumonia can be very severe in otherwise healthy people.

Although a few case reports of *M. pneumoniae* infections in pediatric AIDS patients have appeared in the literature[22] and there has been speculation about a possible role for *M. pneumoniae* as a cofactor in AIDS,[23,24] it is not known if the incidence or severity of pulmonary or extrapulmonary infections in AIDS patients is increased. Hypogammaglobulinemic patients appear to be at increased risk of developing joint and respiratory infections,[24–27] but the overall effect of the immunosuppressed state on host resistance to infections is unclear. There have been reports of transplant recipients becoming susceptible to infection with other species of

mycoplasmas in a variety of sites, and because *M. pneumoniae* may not be killed in donor tissues by antibiotics, there is the possibility that infection could be acquired by transplant recipients on immunosuppressive drugs (reviewed in[28]).

3.2. Laboratory Diagnosis

3.2.1. Clinical Laboratory Diagnosis. Clinical laboratory findings are seldom diagnostic. About one-fourth to one-third of persons with lower respiratory tract infections due to *M. pneumoniae* will have leukocytosis and/or elevated erythrocyte sedimentation rate. Sputum Gram stain may show mononuclear cells or neutrophils and normal flora. There are no hepatic or renal abnormalities typical of mycoplasmal infection, although some patients may develop a hemolytic anemia as one of the numerous extrapulmonary manifestations, and this may be reflected in the hemogram.

3.2.1.1. Cold Agglutinins. Prior to the widespread availability of commercialized antibody assays, and even before the precise bacteriological characterization of the etiological agent was known, clinicians sometimes used the presence of cold agglutinins to confirm their clinical suspicions of primary atypical pneumonia, also known as "cold agglutinin disease". Cold agglutinins are IgM antibodies produced 1–2 weeks after initial infection in about 50% of *M. pneumoniae* infections, sometimes persisting for several weeks. The exact antibodies responsible for cold agglutination are not well characterized; they may be the result of cross-reactive autoantibodies developed against the I antigen of human erythrocytes during acute mycoplasmal infection. Another possibility is that antibodies are directed against erythrocyte antigens altered during infection. The latter possibility is supported by the fact that *M. pneumoniae* is known to interact with and adsorb to human erythrocytes and to produce a hemolysin, and also because cold agglutinins can be induced in rabbits inoculated with human erythrocytes that were preincubated with *M. pneumoniae*, but not in rabbits inoculated with either *M. pneumoniae* or erythrocytes alone.[5]

Two varieties of cold agglutinin determination have been used. The simplest version is referred to as "bedside cold agglutinins." Blood from a patient suspected of having mycoplasmal pneumonia is collected into a tube containing citrate or another suitable anticoagulant, then placed in ice water in a freezer for approximately 30s. The tube is then tilted on its side and examined for coarse agglutination. On warming, the agglutination should resolve, but it can be reproduced by repeating the cooling procedure. More precise testing can be performed using doubling dilutions of patient sera with human type O erythrocytes. The cold agglutinin response often correlates directly with the severity of pulmonary involvement, and patients with extensive lobar involvement will usually have a titer of $\geq$32. In contrast, those with only minimal illness may not develop cold agglutinins.

Cold agglutinins also occur in persons who have various bacterial and rickettsial infections as well as in those with influenza virus and adenovirus infections. Due to the availability of antibody assays that are based on immunological reagents specific for *M. pneumoniae*, the popularity of testing serum for the presence of cold agglutinins has declined. If used, this test should be limited to persons in whom mycoplasmal pneumonia is a strong possibility. Under these circumstances, a positive test provides reasonable supportive evidence of a mycoplasmal etiology, on the basis of which clinical management decisions can be made.[5,29]

3.2.1.2. Culture. Culture of *M. pneumoniae* from the respiratory tract and other body sites is laborious and expensive, requiring serial blind passages, specialized and expensive growth media, and incubation periods of up to several weeks. SP4 medium ("SP" for "spiroplasma"), developed over 20 years ago by Tully et al.,[30] has become the most successful and widely used broth and agar medium for cultivating *M. pneumoniae* for clinical purposes. It is sold commercially in the United States by Remel Laboratories (Lenexa, Kansas). Detection of *M. pneumoniae* by culture is predicated on its characteristic hydrolysis of glucose, with a resultant acidic shift, after 4 days or more of incubation in broth containing a phenol red pH indicator. Initial specimens, as well as broths with color change and blind subcultures, should be transferred to SP4 agar, incubated, and examined under a stereomicroscope at regular intervals to look for development of spherical colonies of up to 100 μm in diameter (Figure 1).

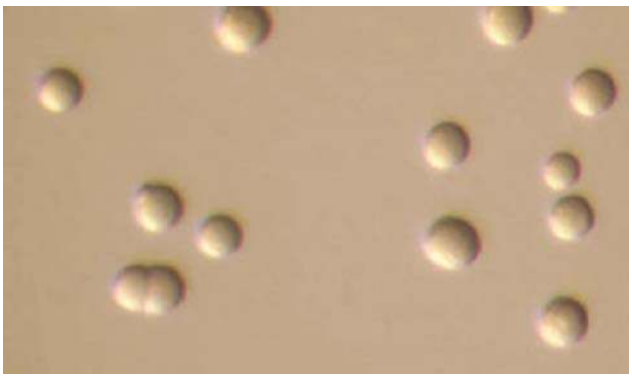

Figure 1. Spherical colonies of *M. pneumoniae* growing on SP4 agar at a magnification of ×95. Reprinted with permission from authors and American Society for Microbiology.[5]

Incubation of *M. pneumoniae* broth cultures under atmospheric conditions at 37°C is satisfactory, but agar plates will yield the best colonial growth if 5% CO_2 is provided and plates are sealed to prevent loss of moisture during prolonged incubation. A biphasic medium consisting of an agar slant in a screw-cap bottle to which broth is added is sold by Irvine Scientific in the United States under the trade name Mycotrim RS.[5,31,32]

Compared to molecular techniques such as PCR, the analytic sensitivity of culture may be no more than 60% in experienced laboratories, even when rigorous adherence to procedures known to enhance cultural isolation are used.[33] However, when positive, culture has the advantage of being 100% specific, provided that appropriate additional procedures are used to identify the organism isolated to species level. Although there is good evidence that disease is associated with increased numbers of bacteria in the upper respiratory tract,[34] the persistence of *M. pneumoniae* for variable lengths of time following acute infection makes it difficult in some cases to assess the significance of a positive culture or assay without additional confirmatory tests such as serology. For the reasons cited above, culture is rarely used for routine diagnosis and/or management of *M. pneumoniae* infections. In view of the many limitations of culture for detection of *M. pneumoniae*, if attempted it should be augmented by additional diagnostic methods such as PCR and/or serology.

3.2.1.3. Serology. Commercial *M. pneumoniae* antibody detection kits which utilize passive (particle) agglutination, indirect immunofluorescence, or enzyme-linked immunofluorescent assay (EIA) formats are available for the detection of antibodies to *M. pneumoniae* in human sera (reviewed in[31]).

The strategy for serologic diagnosis of *M. pneumoniae* was strongly influenced by early assumptions that mycoplasmas were viruses. This led to the development of complement fixation (CF) tests for *M. pneumoniae* diagnosis. The sensitivity and specificity of CF tests for viral infections are due in part to the relatively low number of viral antigens, which reduces the chances of cross-reactivities. Because of the much larger complement of bacterial antigens, the CF test for *M. pneumoniae* suffers from decreased sensitivity and specificity, limiting its usefulness in serologic testing,[4,31,32,35] and with the wide variability in performing and interpreting CF assays between laboratories, CF is no longer widely utilized. Most laboratories have replaced the CF assay with EIAs due to their ease of use and decreased run time. Of the various test formats, EIA is the most widely used and the most adaptable to most clinical laboratory settings.[35–37]

EIA is a valid methodology for detecting IgM antibodies to *M. pneumoniae* using acute-phase serum from some patients with suspected cases of *M. pneumoniae* infections.[38–40] This approach has a theoretical advantage because only one specimen is required, and IgM can be detected approximately 7–10 days after the onset of infection. However, a major limitation of an IgM-specific test is that detectable levels of IgM antibodies may not be present if the serum sample is obtained too early in the infection, and only 14–27% of acute-phase sera from confirmed adult patients may test positive by the various IgM kits. The number of IgM-positive sera from confirmed cases rises to 39–88% when convalescent-phase sera are tested.[36]

Alternately, specific IgM in adults does not always indicate an acute infection because it can persist for up to a year after infection with *M. pneumoniae*.[41,42] To further complicate matters, an IgM response may be either minimal or undetectable when adults are reinfected. In previous studies, approximately 20% of adults did not mount an IgM response after infection with *M. pneumoniae*.[35,43] Therefore, relying exclusively on the detection of specific IgM (especially in an adult population) will result in the misdiagnosis of some infections. Measurement of IgA, which may rise and fall sooner than IgM or IgG, can be useful for detection of acute *M. pneumoniae* infection, especially in older persons, but reagents to detect this antibody are available in very few commercial tests at the present time. A comprehensive review of the value of serology for the detection of *M. pneumoniae* in the clinical laboratory has been published by Waites et al.[32]

3.2.1.4. Antigen Detection. Rapid assays for detection of (non-nucleic acid) *M. pneumoniae* antigen in respiratory tract specimens have included direct immunofluorescence, counterimmunoelectrophoresis, immunoblotting, and antigen capture enzyme immunoassay. The utility and general acceptance of these techniques have been reduced by low sensitivity and cross-reactivity with other mycoplasmas found in the respiratory tract. Non-amplified antigen detection assays are at the limit of sensitivity for detection and are not recommended for diagnostic purposes when superior technology utilizing nucleic acid amplification is available. Although not sold in the United States at present, commercial antigen detection tests for *M. pneumoniae* are available in some European countries.[44–46]

3.2.1.5. Nucleic Acid Detection. Development of molecular-based testing such as the polymerase chain reaction (PCR) assay has lessened the importance of culture as a means for detecting *M. pneumoniae*. Studies since the late 1980s using simulated clinical specimens, animal models, and later clinical trials have validated the ability of PCR to detect *M. pneumoniae*, often in conjunction with serology and/or culture (recently reviewed in[5]). The same types of clinical specimens that can undergo culture can also be tested

by PCR. The use of two different targets can maximize the ability to detect the organism. The conventional PCR procedure currently used at the Centers for Disease Control and Prevention has been adapted from the procedure originally described by Bernet et al.[47] using primers derived from the *M. pneumoniae* ATPase gene. They have also developed a real-time PCR which targets this gene. Other sequences, primarily the P1 adhesin and conserved regions of 16S rRNA, have also been utilized. For additional information and tabulations of various nucleic acid amplification assays according to respiratory specimen tested, or by publication with or without validation data, the reader is referred to three recent publications on this topic.[48–50] Among the other advantages of PCR are that it can be used to detect mycoplasmas in tissue that has already been processed for histological examination or in cultures that are contaminated. PCR requires only one specimen, the assay can be completed in 1 day, it may provide a diagnosis earlier in infection than serology, and it does not require viable organisms. Specific advantages of RNA-based amplification techniques are the high sensitivity that can be achieved due to the large number of rRNA copies per mycoplasmal cell and the fact that its detection may be more indicative of viable mycoplasmas in a clinical sample.[48]

3.3. In Vitro Antibiotic Susceptibility Testing

M. pneumoniae is inhibited by tetracyclines, macrolides, ketolides, and fluoroquinolones, with little variation in MICs among clinical isolates.[51,52] Thus, in vitro susceptibility testing is not indicated for routine patient management purposes for infections of the respiratory tract. Additional agents that are active at the bacterial ribosome, such as streptogramins, chloramphenicol, and aminoglycosides, may also show in vitro inhibitory activity against *M. pneumoniae* but are not widely used for therapeutic purposes against this organism. Clindamycin may be effective in vitro, but limited reports suggest that it may not be active in vivo, and it has not been considered a first-line treatment.[53] Due to the lack of a cell wall, all mycoplasmas are innately resistant to all beta-lactams and glycopeptides. Sulfonamides, trimethoprim, polymyxins, nalidixic acid, and rifampin are also inactive. Linezolid is the prototype agent of the oxazolidinone class. These agents are much less active against *M. pneumoniae* than the other agents that inhibit protein synthesis.[54]

New quinolones such as moxifloxacin, gemifloxacin, and sparfloxacin tend to have somewhat greater in vitro activity than older agents such as ciprofloxacin, ofloxacin, and levofloxacin, although MICs of all fluoroquinolones are several-fold higher than those of macrolides.[51,52,54,55] Fluoroquinolones have been shown to be bactericidal for *M. pneumoniae*, whereas macrolides and tetracyclines are primarily bacteriostatic.[51,55–57]

The extent of naturally occurring, clinically significant acquired antimicrobial resistance of *M. pneumoniae* to any drug class is not known, but historically has been believed to be uncommon. Strains resistant to tetracycline and erythromycin have been isolated but are still believed to be uncommon in the United States, even though there has been a recent increase in macrolide resistance in Japan since 2000 due to 23s rRNA mutations which may have some clinical significance.[5] Recent studies evaluating macrolides, tetracyclines, or fluoroquinolones indicate comparable in vitro activities against isolates obtained from North America and Europe, with no change from data reported earlier other than some minor variations that may be due to differences in testing methods, media, and inocula, although some macrolide-resistant isolates from the United States and France are known to occur.[51,58–60] Since organisms from acute *M. pneumoniae* infections are seldom sought by culture, they are almost never tested for in vitro susceptibilities for clinical purposes, and most in vitro studies reported to date tested relatively small numbers of clinical isolates from limited geographic areas. Older studies reported that organisms can be shed in respiratory secretions for long periods after acute infection and that high-level, macrolide-resistant strains can be isolated following erythromycin treatment.[61,62]

4. Etiologic Patterns

4.1. *M. pneumoniae* Syndromes

It is important to realize that *M. pneumoniae* infection can present as a very wide variety of clinical manifestations. A brief summary is provided in Table 2.

4.1.1. Pneumonia. The radiographic findings in *M. pneumoniae* pneumonia can be extremely variable and mimic a wide variety of lung diseases, but sometimes the radiologic appearance coupled with clinical manifestations can give clues to a mycoplasmal etiology. The inflammatory response elicited by *M. pneumoniae* causes interstitial mononuclear inflammation in the lungs that may be manifest radiographically as bronchopneumonia.[63]

4.1.2. Asthma. Multiple reports suggest that *M. pneumoniae* infections are associated exacerbations of asthma,[29,64–67] although this finding is not universal.[65,68] The more important question is whether mycoplasmas are a primary cause of asthma or if mycoplasma infection is a cofactor in asthma development. Multiple lines of evidence suggest that *M. pneumoniae* may play a role beyond simple and acute exacerbation. *M. pneumoniae* can be recovered

Table 2. Manifestations of *Mycoplasma pneumoniae* Infection

Respiratory	**Common secondary**
Pneumonitis/pneumonia	Erythematous maculopapular, other rashes
Bronchitis, tracheobronchitis	Thrombocytopenia
Bronchiolitis	Meningitis – encephalitis
Tracheobronchitis	Mild anemia
Pharyngitis	Asthmatic bronchitis
	Otitis externa, interna
Neurological	**Less common secondary**
Meningitis	Hemolytic anemia
Encephalitis	Disseminated intravascular coagulation
Psychosis	Thromboembolism
Guillain–Barré syndrome	Pericarditis, myocarditis, pericardial effusion
Cerebellar ataxia	Glomerulonephritis, renal failure
Brain-stem syndrome	Arthritis, polyarticular and septic
Poliomyelitis-like syndrome	Erythema nodosum
Transverse myelitis	Stevens–Johnson syndrome
Focal encephalopathy	Conjunctivitis

more often from the airways of patients with chronic, stable asthma than from matched control patients,[69–71] and reductions in lung function tests 1 year,[72] 3 years,[73] and up to 9 years or more[74] after an episode of mycoplasma respiratory tract infections have been reported, thus establishing the ability of mycoplasmas to induce chronic to permanent lung damage long after resolution of respiratory tract symptoms. Similarly, bronchial hyperreactivity to methacholine challenge was present in 50% of patients 12 weeks after recovering from mycoplasma pneumonia compared with none in controls.[75] *M. pneumoniae* is known to induce a number of inflammatory mediators implicated in the pathogenesis of asthma. A variety of mediators (including IgE) are induced at high levels by mycoplasma infection and may play a role in exacerbations, which often include wheezing.[71,76,77]

Although a delay in initiation of proper antibiotic therapy may be a risk factor for potentially permanent reductions in lung function,[72] conflicting reports in the literature suggest that much more research is needed to determine the true role of *M. pneumoniae* in the initiation and chronicity of asthma.

4.1.3. Extrapulmonary Syndromes. Reports of extrapulmonary *M. pneumoniae* complications have appeared in the literature for over 60 years. Although the complications can be grouped roughly by organ system for ease of discussion, it is important to realize that often multiple organ systems are involved, and hematogenous spread to many organ systems in the same patient is well known.[21,78,79] It is very important to realize that extrapulmonary complications can be seen before, during, or after pulmonary manifestations or even occur in the complete absence of any respiratory symptoms.[80]

4.1.3.1. Neurologic. *M. pneumoniae* CNS infections can be severe and life threatening and are more common than generally perceived. In a study of 462 children with acute encephalitis, patients with *M. pneumoniae* infection were seven times more likely to die or have severe neurologic sequelae than were other children in the cohort,second only to herpes simplex virus.[81] In a 5-year prospective study of 159 children with encephalitis, 20 (13%) were characterized as probable or possible cases of *M. pneumoniae*, but only 13 of the 20 (65%) had prodromal respiratory signs and symptoms, which ranged from 4 weeks to several days prior to the onset of clinical encephalitis.[82] Others have found that the incidence of prior respiratory illness in children diagnosed with *M. pneumoniae* CNS infections ranges from 20 to 80%.[83] These findings emphasize that the absence of respiratory illness prior to the onset of encephalitis does not rule out involvement by *M. pneumoniae*.

In children, most CNS infections attributed to *M. pneumoniae* manifest as encephalitis (diffuse, local, or expansive). However, a wide range of disease syndromes in adults and/or children have been reported, including encephalitis, post-infectious encephalomyelitis with demyelination, acute disseminated encephalomyelitis, meningoencephalitis, meningitis, transverse and diffuse myelitis, Guillain–Barré syndrome, Bickerstaff's brain-stem encephalitis, Fisher's syndrome, and cranial (as well as peripheral) nerve neuropathy, including optic neuritis. In addition, cerebellar syndrome, coma (with or without evidence of meningoencephalitis), stupor, ataxia, athetosis, psychosis, diplopia, mental confusion, transient extreme spindles (secondary to subacute encephalitis), status epilepticus, grand mal seizure, and athetotic/choreoathetotic movements have been reported as concurrent manifestations or sequelae.[84–87]

M. pneumoniae infection can induce antibodies against the galactocerebroside (Gal-C) component of myelin in 25% of patients without CNS involvement and in 100% of patients with such involvement. High anti-Gal-C antibody titers have been reported in cases of profound spinal cord degeneration and decerebrate rigidity and coma subsequent to mycoplasma respiratory tract infections.[88] The mechanism by which anti-Gal-C antibodies are induced by *M. pneumoniae* infection is not known, but the integrity of the blood–brain barrier may be a determining factor in the extent of damage to CNS structures. Alternately, such antibodies may also be induced after CSF invasion, as demonstrated by

the presence of anti-mycoplasma antibodies in the CSF of patients with mycoplasmal infection of the CSF (as demonstrated by culture or PCR).[89]

Numerous reports have documented the presence of *M. pneumoniae* in CSF and/or brain tissue, proving that invasion may occur (reviewed in[6]). However, CNS disease associated with *M. pneumoniae* infection may occur without evidence of CNS invasion, and faced with clear evidence that *M. pneumoniae* can induce anti-myelin antibodies, researchers have postulated that an immune-mediated mechanism (in addition to direct invasion) is involved in CNS disease. Narita et al. expanded on this concept in several reports when they showed that *M. pneumoniae* was detectable by PCR in the CSF of patients more frequently when the onset of CNS symptoms appeared within 7 days of the onset of fever versus 8 or more days.[90–92] They interpreted this temporal data to suggest that two distinct patterns of CNS disease caused by *M. pneumoniae* exist: an early-onset syndrome caused by the presence of bacteria in the CNS and a late-onset syndrome in which the presence of bacteria in the CNS is not necessary to cause disease. Reports of post-infectious leukoencephalopathy with severe sequelae also support a role of autoimmunity in mycoplasmal CNS disease.[93] However, findings by other workers do not neatly fit into this two-pattern model, and much more work is required to determine its validity and usefulness.[94]

Neurologic complications from respiratory *M. pneumoniae* infection may ultimately result from direct infection of brain tissues as well as secondary destruction of tissue caused by the generation of autoimmune antibodies, but only recently have assays evolved to reliably identify low numbers of mycoplasmas in tissues so that this issue can be properly addressed.

In a multi-year CDC program designed to uncover infectious disease diagnoses for patients with unexplained serious illnesses in the United States, *M. pneumoniae* was responsible for cases characterized by primarily neurologic symptoms as well as those with primary respiratory symptoms.[95] For a more detailed review of neurologic diseases caused by *M. pneumoniae*, see reference[6].

4.1.3.2. Cardiac. A variety of cardiac complications have since been reported, including pericarditis, myocarditis, and pericardial effusion with and without cardiac tamponade.[22,25,96–98] Of note, a prospective study of pericardial effusions uncovered two cases of *M. pneumoniae* infection confirmed by isolation of mycoplasmas from pericardial effusion or tissue. An additional two cases of pericarditis due to *M. hominis* (and one due to *Ureaplasma urealyticum*) have also been diagnosed.[99]

In general, cardiac complications are relatively uncommon, occurring in 1–8.5% of patients with serologic evidence of infection, primarily adults.[13] A large 1979 study reported that 4.5% of patients with serologically confirmed cases of mycoplasmal pneumonia had cardiac complications, and almost half of these patients had evidence of symptoms or heart abnormalities an average of 16 months later.[98]

4.1.3.3. Renal. Renal complications associated with *M. pneumoniae* respiratory infections were first reported in the 1970s. Renal diseases such as acute glomerulonephritis and renal failure (sometimes secondary to rhabdomyolysis), tubulointerstitial nephritis, IgA nephropathy, as well as others have been reported sporadically.[79,99–102] Attempts to demonstrate mycoplasma antigen in damaged renal tissue with immunohistochemical techniques have not been uniformly successful, once again leading to theories that an antibody-mediated pathogenesis and not direct infection may be responsible for some cases of renal disease.[100,103] An attempt to use PCR to identify mycoplasmas in renal tissue from four young patients with acute nephritis with serologic evidence of recent *M. pneumoniae* was unsuccessful.[21] Although renal complications of *M. pneumoniae* infection are rare,[21] additional attempts to identify mycoplasmas in kidney tissue using PCR assays are needed to clarify whether direct or indirect damage to tissue is occurring.

4.1.3.4. Arthropathies. Three basic patterns of joint disease associated with *M. pneumoniae* infection have been described: transient polyarticular pain or discomfort centered primarily on the large joints coincident with acute illness, polyarthropathy affecting primarily medium-sized joints that can persist for a year or more after acute illness,[104] and septic arthritis reported most often in hypogammaglobulinemic patients.[26,27,105107] However, in only a few cases had mycoplasmas been cultured from joint fluid until the mid- to late 1980s, when reports of *M. pneumoniae* isolations from joint fluid from immunocompetent patients with polyarthritis appeared.[108] The difficulties of isolating mycoplasmas from affected joints of patients who fit clinical criteria for mycoplasma pneumonia invite suggestions that *M. pneumoniae* and other mycoplasmas may be "cofactors" in arthropathies such that direct invasion of joints may not be necessary.[109] Increased use of PCR assays to detect mycoplasmas from joint fluid and tissues will better establish how often mycoplasmas are really present in joints, but not cultivable. This will help clarify the role of direct invasion.

4.1.3.5. Dermatologic. A variety of dermatologic abnormalities have been associated with *M. pneumoniae* infection in up to 25% of patients.[26] Among the more

common are erythematous maculopapular and vesicular rashes or "exanthems." Most cases associated with pneumonia are self-limiting within about 7 days, and for unknown reasons are most often seen in males.[80] More severe mucocutaneous syndromes have also been reported, including severe conjunctivitis, generalized ulcerative stomatitis, and bullous exanthems.[80,110] Mild to severe forms of Stevens–Johnson syndrome have also been associated with *M. pneumoniae* infections, most often presenting as cases of erythema on the trunk with stomatitis and sometimes conjunctivitis rather than the severe toxic reactions with widespread epidermal necrosis more commonly seen with drug reactions.[111–113] The value of using steroids to treat Stevens–Johnson syndrome caused by *M. pneumoniae* has not been clearly established.[111]

Pediatric patients with pleuropneumonia are more likely to present with dermatologic manifestations than are those with uncomplicated pneumonia.[114] Clinicians should keep in mind that the presence of erythematous maculopapular rashes can also be caused by a number of antibiotics commonly given to *M. pneumoniae* patients.[115]

4.1.3.6. Hematologic. Hemolytic anemia has been recognized as a rare but severe complication of mycoplasma pneumonia since the 1940s.[116] Numerous reports have documented this complication, found in higher incidence among children.[117–119] Hemolytic anemia has been attributed in cold agglutinin disease and autoimmune hemolytic anemia to *M. pneumoniae*-induced cross-reacting antibodies to the I antigen of human erythrocytes.[53,118,120]

One report suggests that thrombotic thrombocytopenic purpura (TTP) sometimes seen in patients with *M. pneumoniae* infection may be the result of cross-reactive antibodies inactivating the plasma von Willebrand factor cleaving protease, resulting in unusually large von Willebrand factor multimers that later on initiate the cascade of TTP.[121] Pediatric cases of aplastic anemia associated with *M. pneumoniae* also have been reported.[122] When subclinical forms of hemolytic anemia and intravascular coagulation are considered, over 50% of patients with mycoplasma infections may be affected.[123]

4.1.3.7. Other Extrapulmonary Syndromes. A variety of less common extrapulmonary infections and sequelae have been reported for *M. pneumoniae*. Although rare, ocular manifestations have been reported, primarily in pediatric cases. Ocular manifestations include conjunctivitis, anterior uveitis, optic neuropathy, retinitis and retinal hemorrhages, iritis, and optic disc swelling, with or without permanent degradation of vision.[124,125]

Up to one-third of patients may have nonspecific ear symptoms, in addition to otitis externa and interna.[112,126] Rarely, hepatitis and pancreatitis have been associated with respiratory infections,[119,127] and *M. pneumoniae* has been isolated from the urogenital tract of males and females as well as cultured from a tubo-ovarian abscess.[128]

5. Descriptive Epidemiology

Epidemics of *M. pneumoniae* infections occur in the community and in closed or semi-closed settings. Military bases,[12,129–132] hospitals,[133–135] religious communities,[136,137] and facilities for the mentally or developmentally disabled have been particularly hard-hit.[138–140] Unlike endemic disease which has no seasonality, outbreaks in the United States tend to occur in the summer or early fall.[12,123,138,139,141]

New recruits on military bases are at particularly high risk of acquiring *M. pneumoniae* infection.[130] In the 1970s, more than half of all recruits acquired an acute mycoplasma infection in some companies.[129] Although the majority of infections are mild, *M. pneumoniae* is a leading cause of bacterial pneumonia among both outpatient and hospitalized military personnel.[131,142]

Outbreaks in closed or semi-closed settings can be very difficult to control for many reasons, including delayed outbreak detection, difficulty of implementing effective infection control practices, and a long incubation period. Attack rates can be quite high, with reports ranging from 25 to 71% in some settings.[12,139,141,143] Figure 2 shows successive peaks of illness in students at a military academy after they returned to school in two major groups. Although long-term morbidity is uncommon, these outbreaks can be very disruptive and can consume large resources. Strategies to control these outbreaks have included cohorting and using antibiotic therapy for symptomatic persons. A number of trials of prophylactic antibiotics have been tried with varied success. Many of these studies were longitudinal in nature, making it difficult to determine whether the interventions were effective or whether all susceptible persons had been exhausted. In one recent study, a placebo-controlled trial of azithromycin prophylaxis in a hospital for developmentally impaired adults, therapy demonstrated a protective efficacy of 75% against illness resulting in physician visits among hospital employees.[138] In selected circumstances, the use of prophylactic antibiotics may be an effective tool for control of mycoplasma outbreaks in closed settings.

5.1. Geographic Distribution

Infection with *M. pneumoniae* is worldwide, although careful survey studies have not been performed in most countries.

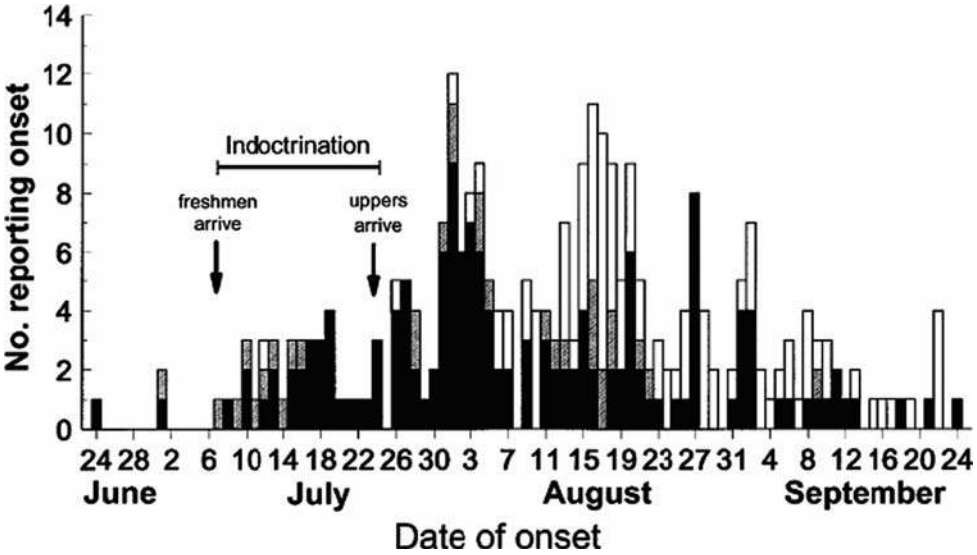

Figure 2. Outbreak of "mycoplasma-like" illness at a federal training academy. Shown is date of onset of illness among students presenting to clinic with condition (n = 273) during an outbreak at a federal service training academy, June–September 1996. Black bars, freshman; grey bars, upperclassmen (uppers) at indoctrination; white bars, remaining upperclassmen. Freshman and some upperclassmen arrived for indoctrination, then 15–18 days later most upperclassmen arrived. The major peaks of illness were centered around the end of June and beginning of August for freshman, then about 15–18 days later in the middle of August for upperclassmen. Used with permission by the author and University of Chicago Press.[12]

5.2. Age Distribution

The incidence of mycoplasma pneumonia is greatest among school-aged children and declines after adolescence.[143,144] Rates of disease among children under 5 years have been reported to be low, but these studies were conducted at a time when out-of-home child care was less common. It is likely that the rate among preschool children is higher than once thought because of the ease with which young children share respiratory secretions.

Although most mycoplasma infections occur among outpatients, *M. pneumoniae* is a significant bacterial cause of hospitalizations for pneumonia in the United States, especially among the elderly.[15] Most reports of severe complications and deaths from mycoplasma infection occur in this age group. Children may also represent an asymptomatic reservoir of infection for outbreaks in families.[145]

5.3. Transmission in Families

Mycoplasma infections are frequently spread among family members.[145–149] In a recent study in the Netherlands, 15% of family members of *M. pneumoniae*-positive index patients had organisms isolated from their nose or throat within 4 weeks of the index case.[145] The frequency of transmission within families was the same regardless of the appropriateness of the antibiotic used for treatment of the index patient. The frequency of transmission reported in this study probably represents a marked underestimate of the risk of transmission within families, given that other studies have shown that several cycles of 3–4 weeks may be necessary before intrafamily transmission is complete. In a study in Seattle, 39% of family contacts eventually became infected, many asymptomatically.[148]

6. Mechanisms and Routes of Transmission

Transmission of *M. pneumoniae* usually requires close contact, such as in a family residence or in an institutional setting with a high density of people. Transmission is believed to be by respiratory aerosols or droplets.

7. Pathogenesis and Immunity

7.1. Incubation Period

In view of the intimate contact needed for droplet transmission and the slow 6-hour generation time of *M. pneumoniae*, 1–3 weeks incubation for each case is typical (see

Figure 2). In families, several cycles of infection may be necessary before intrafamily transmission is complete. Some studies have reported incubation periods from common source outbreaks as short as 4 days,[150] whereas others have reported longer incubations with a median of 23 days with intrafamilial spread where smaller inocula may be involved and transmission may be less effective until the index case has exhibited symptoms for several days.[148]

7.2. Pathogenesis

M. pneumoniae is a mucosal parasite primarily involving the upper and lower respiratory tract, but it has been isolated and/or demonstrated by PCR in other sites including the urogenital tract, cerebrospinal fluid, synovial fluid, pericardial fluid, and cutaneous lesions.[5] In postmortem examinations, *M. pneumoniae* has been recovered from the blood in the heart and pericardial sac,[151] spleen, brain, and kidney.[79] However, the frequency of direct invasion of these sites is unknown because the organism is rarely sought for clinical purposes. *M. pneumoniae* can be isolated from the pharynx 1 week prior to onset of clinical illness; recovery rates are highest during the first week of illness, shedding from the pharynx subsequently decreases, but prolonged carriage may occur in an unknown percentage of persons. The organism has been recovered as late as 4 months after the onset of illness and for a much longer period in hypogammaglobulinemic patients.[152]

Attachment of *M. pneumoniae* to the respiratory epithelium by its specialized attachment organelle is a prerequisite for later events that culminate in production of disease.[4] The close interaction between the mycoplasma and host cells protects it from removal by the host's mucociliary clearance mechanism and allows it to produce a variety of local cytotoxic effects. The attachment organelle consists of a specialized tip structure with a central core of a dense rod-like central filament surrounded by a lucent space that is enveloped by an extension of the organism's cell membrane. The tip structure is actually a network of adhesins, interactive proteins, and adherence accessory proteins that cooperate structurally and functionally to mobilize and concentrate adhesins at the tip of the organism. Attachment organelles can be seen in a scanning EM photograph in Figure 3.

The P1 adhesin is a 170-kDa protein concentrated in the attachment tip that is now known to be the major structure responsible for interaction of *M. pneumoniae* with host cells.[5] A variety of proteins are believed to participate in the establishment of the polar structure. Once this polar structure is established, an independently assembled complex of proteins B, C, and P1 is drawn to the structure to complete formation of the functional terminal attachment organelle.[153] Attachment has been studied in detail in the hamster model and in tracheal organ culture. Ciliary movements ceased after a couple of days; the latter effect was not observed with nonpathogenic mycoplasmas. An infiltrate adjacent to the bronchial regions consisted primarily of mononuclear cells and some cells defined as plasma cells.[154]

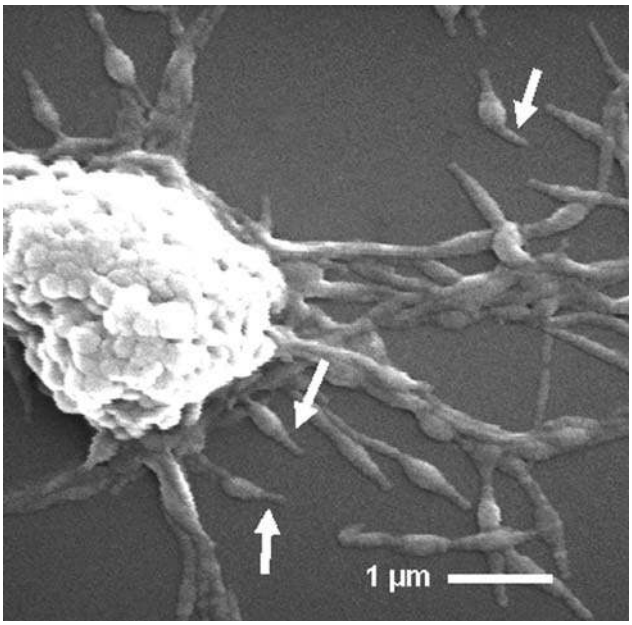

Figure 3. Scanning electron microscopic image of *M. pneumoniae* cells. A large clump of cells is present to the left. Individual cells with attachment tip organelles (*white arrows*) and typical morphology are seen (courtesy J. Carr, Centers for Disease Control and Prevention).

An important area of research is whether intracellular infections of host cells by *M. pneumoniae* and other mycoplasmas is an important factor in pathogenesis. An intracellular existence could facilitate the establishment of latent or chronic states, circumvent mycoplasmacidal immune mechanisms, facilitate the organisms' abilities to cross mucosal barriers, gain access to internal tissues, and impair efficacy of some drug therapies, accounting for difficulty in eradication.[154–157] Fusion of the mycoplasmal cell membrane with that of the host could result in release of various hydrolytic enzymes produced by the mycoplasma as well as insertion of mycoplasmal membrane components into the host cell membrane, a process that could potentially alter receptor recognition sites, affect cytokine induction and expression, and provide a mechanism for post-infectious autoimmune reactions. At present, the extent to which *M. pneumoniae*invades and replicates intracellularly in vivo is not known. Therefore, the clinical significance

of these theoretical events associated with cell fusion remains to be proven.

Close approximation of the organism to the host cells facilitated by the adhesin proteins appears to be important to facilitate localized tissue disruption and cytotoxicity. Hydrogen peroxide and superoxide radicals synthesized by mycoplasmas act in concert with endogenous toxic oxygen molecules generated by host cells to induce oxidative stress in the respiratory epithelium.[154] Hydrogen peroxide has been known to be important as a virulence factor in *M. pneumoniae* since Somerson showed it to be the molecule that confers hemolytic activity.[158] The ultrastructural effects of peroxide on host cells such as erythrocytes include loss of reduced glutathione, denaturation of hemoglobin, peroxidation of erythrocyte lipids, and eventually lysis of the cells. Superoxide anion produced by *M. pneumoniae* acts to inhibit catalase in host cells, thereby reducing the enzymatic breakdown of peroxides produced endogenously and rendering the host cell more susceptible to oxidative damage.[159]

Although the number of fatalities due to *M. pneumoniae* infection coming to autopsy is small, the postmortem findings are similar to those seen in the hamster model: interstitial infiltrates surround bronchi and bronchioles.[5] The infiltrates consist primarily of mononuclear cells, especially macrophages, lymphocytes, and plasma cells. The alveolar lining cells are swollen. Exudate, consisting of fibrin and leukocytes, has been observed primarily in the bronchial spaces.

7.3. Immunity

Elements of the host innate immune system are activated by *M. pneumoniae* and the attendant inflammation accounts for many of the initial signs and symptoms accompanying the early stages of the evolving infection. Upon reaching the lower respiratory tract, the organism may be opsonized by complement or antibodies. Macrophages become activated, begin phagocytosis, and undergo chemotactic migration to the site of infection. Therefore, it is possible that complement plays a significant role in inhibiting growth of the organism, particularly after inflammation induces infiltration by inflammatory cells and exudation.[160,161]

Adaptive immunity by both B and T lymphocytes has a major impact on the progression of mycoplasmal respiratory disease. But immunity is often short-lived, and humans are susceptible to repeated infections despite the development of complement-fixing and growth-inhibiting antibody responses. Immune responses that develop after infection often fail to eliminate the organisms, implying that adaptive immunity can have a limited effect on the clearance of an established infection, thus allowing asymptomatic carriage.[162]

Cytokine production and lymphocyte activation can reduce infection and reduce inflammation or exacerbate disease through the development of immunologic hypersensitivity, resulting in damage to the respiratory epithelium and deeper tissues. Lymphoid infiltrations undoubtedly contribute to the development of inflammatory responses. CD4+ T lymphocyte, B lymphocyte, and plasma cell lung accumulations in the lung result in radiographic manifestation of pulmonary infiltrates and are associated with production of immunoglobulins and the release of a variety of cytokines.[163]

8. Patterns of Host Response

8.1. Clinical Features

Host response to *M. pneumoniae* ranges from asymptomatic infection to pharyngitis, bronchitis, bronchiolitis, croup, tracheobronchitis, pneumonitis, and pneumonia (Table 2). The onset of mycoplasma pneumonia is usually insidious, in contrast to the abrupt onset of classic pneumococcal pneumonia. The symptoms include chills (55%), headache (66%), sore throat (54%), malaise (89%), and cough (99%). The disease may mimic infections caused by *C. pneumoniae*, various viral respiratory diseases such as adenovirus and influenza, and even the common cold. In contrast to most viral respiratory diseases, frank coryza is infrequent. Cough is characteristically non-productive and irritating at onset and may be paroxysmal. In young children, it may have a staccato character and be exaggerated at night. Wheezing is common.

A great variety of respiratory and non-respiratory complications have been described in Section 4, Etiologic Patterns.

8.2. Diagnosis

A diagnosis of mycoplasma pneumonia should be suspected in persons with gradual onset of classical clinical respiratory signs. The white blood cell count is usually normal or slightly elevated and the sedimentation rate may be high, but there are no routine laboratory tests that will provide a specific diagnosis. Dullness is rarely present on examination of the chest, since consolidation is seldom complete. Only a few rales may be heard despite an extensive infiltrate on the chest film. The radiological infiltrate is more often unilateral (84%) than bilateral. It is often described as segmental and patchy and with punctate mottling. Hilar infiltrates are common and characteristically fan out in a wedge-shaped

manner, but any configuration and location of the infiltrate is possible, including upper lobar infiltrates.[5]

Epidemiological clues may be helpful in making the diagnosis of mycoplasma pneumonia because pneumonia of other etiologies is infrequent among persons 15–29 years of age, and a high proportion of pneumonia is due to *M. pneumoniae* in this age group. Likewise, a high proportion of pneumonia encountered in the summer is due to *M. pneumoniae*, because other respiratory agents are then at a low ebb. A history of other family members or contacts having had similar disease about 3 weeks previously is also suggestive.

Isolation of *M. pneumoniae* from respiratory secretions, throat, or nasopharyngeal swabs of individuals with classic respiratory signs is diagnostic, although serologic or other confirmatory tests are useful. However, it may take 4 weeks or longer for the laboratory to grow the organism, and culture is often available only in reference laboratories. Relative advantages and disadvantages of culture, PCR, and serology for specific diagnosis of *M. pneumoniae* infections have been described in previous sections.

9. Control and Prevention

9.1. Treatment

Treatment with tetracyclines, macrolides, and ketolides shortens the duration of illness in *M. pneumoniae* pneumonia. Fluoroquinolones such as levofloxacin, gatifloxacin, and moxifloxacin are also effective.[5] Despite the patient's clinical improvement, shedding of the organisms can continue unabated. Although antibiotic treatment does not eradicate the organism, it is possible that the number of excreted organisms decreases. Patients with hemolytic anemia may require transfusion of blood, preferably I-erythrocytes (anti-I can be associated with cold agglutinin hemagglutinin disease), and the blood should be warmed to prevent hemolysis due to cold agglutinins in the host.

Because of the evidence for an immune component in some cases of *M. pneumoniae* CNS disease and because of the benefits of steroid therapy in many CNS syndromes, steroids are frequently used in combination with antibiotics to treat *M. pneumoniae* CNS infections. A 2002 review of steroid therapy in mycoplasma CNS cases suggests that it is often beneficial, particularly in severe cases. Of 14 cases of severe mycoplasma CNS disease, 11 (78%) were reported to have a complete or near-complete recovery, a better outcome than a report on an earlier series of patients who did not receive steroids.[164] Another report documents successful recoveries in patients with fulminant CNS disease that received high-dose steroid therapy early in the course of disease, leading to suggestions that steroid therapy be initiated early in the course of illness.[165] Although full recoveries are reported, several case reports document patients who relapsed with clinical signs following cessation of a first round of steroids.[83,164] This led Carpenter to suggest the use of a long taper period when steroids are used.[164]

9.2. Vaccines

Interest in development of a vaccine for *M. pneumoniae* has been evident since the early 1960s, soon after the organism was successfully isolated in culture. This interest was fostered by the lack of natural protective immunity following primary infection, prolonged carriage, and propensity for outbreaks of infections in military camps, schools, and hospitals. Development of a vaccine also seemed promising in view of the fact that the organism is rather homogeneous antigenically and there appears to be some protection against reinfection.[5,166,167] Animal models have been used extensively to improve understanding of the natural immune response to *M. pneumoniae* infection and how it might be modified by immunization.[168–179] Ellison provided an in-depth discussion of protective antigens, protective immune mechanisms, and prior vaccine strategies for *M. pneumoniae*, summarizing the work performed in this area through the early 1990s.[180]

Considering that attachment and initiation of local damage at the cellular and subcellular levels are responsible for *M. pneumoniae* disease, the logical vaccine strategy is to prevent attachment and thereby prevent initiation of disease. The initial studies in human volunteers used formalin-inactivated vaccines, but their protective efficacy results were generally disappointing for a variety of reasons that have been explored in-depth by Ellison.[180] Perhaps the most significant event related to volunteer immunizations was the experience of some immunized volunteers who developed more severe illness after experimental challenge with live mycoplasmas. This occurrence has also been documented in animal models after administration of inactivated as well as component vaccines,[180,181] signifying that immunization sensitizes the host in some way through a cell-mediated immune response. Development of live attenuated vaccines administered intranasally or by aerosol inhalation in animal models showed some protective efficacy against disease when rechallenged with virulent strains, suggesting that stimulation of local mucosal defense mechanisms is important.[160,174,180] Development of a serum antibody response after mucosal immunization may or may not occur, depending on the immunogen.[170,173,180] Live attenuated vaccines have never made it to human use due to concern

over residual virulence of the vaccine strain of *M. pneumoniae*. Similar problems were encountered with temperature-sensitive mutant vaccines.[169,180] Other vaccine candidates have included acellular protein and polysaccharide components and recombinant DNA.[182–186] The importance of the P1 adhesin in mediating *M. pneumoniae* cytadherence and initiation of disease is clear, but animal studies using P1 as a vaccine antigen have not demonstrated protective efficacy.[160,180,187,188] Experimental animal studies involving mice,[173,175] hamsters,[178] guinea pigs[189] and chimpanzees[174,178] have continued, but to our knowledge there have been no recent clinical trials in humans with any newer versions of *M. pneumoniae* vaccines and no such trial appears to be forthcoming soon.

10. Unresolved Problems

Clinical trials of new antimicrobial agents for community-acquired pneumonias such as the new macrolides and quinolones have rarely included specific procedures for mycoplasma detection, and those that did often used indirect measures of infection such as serology. Consequently, a better test of "cure" is needed to develop optimal antibiotic treatment therapies for mycoplasmal pneumonia.

The pathogenesis of extrapulmonary syndromes attributed to *M. pneumoniae* infections needs further investigation. Are such syndromes related to direct invasion or immunologic sequelae? It seems likely that either mechanism may occur.

PCR offers promise as a tool for antibiotic trials and studies of extrapulmonary syndromes as well as more rapid diagnoses, but methods need to be standardized and made commercially available for widespread use. Several products are already sold commercially in Europe, but none are available so far in the United States.

Considering not only the respiratory disease caused by *M. pneumoniae* but also the many complications, a vaccine seems desirable and should be encouraged.

11. Other Human Mycoplasmas

11.1. Background, Classification, and Disease Associations

In 1954 Shepard provided the first description of "T-strain" ("T" for tiny) mycoplasmas, later known as ureaplasmas, when he was able to cultivate them in vitro from the urethras of men with nongonococcal urethritis (NGU).[190] *M. genitalium* was first described in the early 1980s when it too was isolated from the urethras of men with NGU.[191] *M. fermentans* is an organism which may play a role in human disease in some circumstances. Evidence has accumulated in recent years to suggest that it may have an etiologic role as an opportunist in persons with HIV infection and AIDS or other immunocompromised persons (reviewed in[31]) and a possible association with chronic arthritic conditions.[192,193] Other organisms such as *M. penetrans* appear to have the potential for being human pathogens,[194] but no conclusive proof demonstrating this has been offered to date. The most recent human mycoplasmal species to be recognized is *M. amphoriforme*, an organism that has been detected in the lower respiratory tract of several immunocompromised persons in association with chronic bronchitis, and investigations are now underway to determine whether a role in human disease can be established with certainty.[195]

Ureaplasma spp. can be found on the mucosal surfaces of the cervix or vagina of 40–80% of sexually mature asymptomatic women, whereas *M. hominis* may occur in 21–53%. The incidence of each is somewhat lower in the urethra of males. Colonization is linked to younger age, lower

Table 3. Diseases Associated with or Caused by *Ureaplasma* Species, *Mycoplasma hominis,* and *Mycoplasma genitalium* in Humans

Disease	*Ureaplasma* spp.	*M. hominis*	*M. genitalium*[a]

− no association or causal role demonstrated.
+ causal role
± association and/or strong suggestive evidence, but causal role not proven in prospective studies
[a] In the case of *M. genitalium,* lack of disease association may reflect the fact that insufficient studies using appropriate detection techniques have been attempted.

socioeconomic status, sexual activity with multiple partners, African-American ethnicity, and oral contraceptive use.[196]

There is now ample evidence that *M. hominis*, *M. genitalium*, and *Ureaplasma* spp. play etiological roles in a variety of urogenital diseases of men and women as summarized in Table 3. For some conditions such as NGU for *Ureaplasma* spp. and pelvic inflammatory disease (PID) for *M. hominis*, Koch's postulates have been fulfilled and a portion of clinical cases of these entities are known to be caused by these respective organisms.[197] However, attempts to link inflammatory diseases of the upper urogenital tract with isolation of the organisms in the lower tract are not always successful, complicating our understanding of their significance as pathogens in many conditions. The discrepancy sometimes observed between the presence of genital mycoplasmas that frequently inhabit the lower urogenital tract in healthy persons and disease in the upper tract is apparently due to the fact that upper tract colonization and disease occur in only a subpopulation of persons who are colonized in the lower tract and that the reasons and risk factors for such upper tract involvement are unknown.[197]

Soon after ureaplasmas were first identified and characterized it became apparent that these organisms could be subclassified into several distinct serovars. The number of serovars was eventually expanded to 14.[198] Additional study over several years, using data obtained from 16S rRNA sequencing, led to the further breakdown of the 14 serovars into 2 biovars or clusters. Biovar 1, also known as the parvo biovar, contains serovars 1, 3, 6, and 14, while biovar 2, also known as the T960 biovar, contains serovars 2, 4, 5, 7, 8, 9, 10, 11, 12, and 13. Recently, the two biovars were designated as distinct species. Biovar 1 became *U. parvum* and biovar 2 became *U. urealyticum*.[199–204] *U. parvum* is the more common of the two biovars isolated from clinical specimens, but both species may occur simultaneously in some people.

Availability of powerful typing techniques such as the PCR assay and a shift in focus from the serovar level to the biovar or species level has led to new information concerning differential pathogenicity among ureaplasmal strains in several recent studies. There was no difference in pregnancy outcome and magnitude of intra-amniotic inflammatory response, chorioamnionitis, birthweight, or gestational age at delivery or neonatal morbidity in women whose amniotic fluid contained ureaplasmas detected by PCR attributable to biovar.[205] However, Deguchi found a significantly higher prevalence of *U. urealyticum* as compared to *U. parvum* in NGU for which prevalence was not significantly different from men without NGU.[206] They also determined it was only certain serovars of *U. urealyticum* that were associated with NGU in a subsequent study.[207] *U. urealyticum* has also been found to be dominant in patients with PID, as well as in patients who had had a miscarriage, and it seemed to have more adverse effects on pregnancy outcome, as assessed by birth weight, gestational age, and preterm delivery, than did *U. parvum* according to a study performed in Germany.[208]

Some studies have been unable to attribute a greater risk of developing bronchopulmonary dysplasia (BPD) among ureaplasma-colonized infants and also found no differences between infants harboring *U. parvum* as compared to those with *U. urealyticum*.[209] However, others have reported that 56% of infants colonized by *U. urealyticum* developed bronchopulmonary disease versus 25% of infants with *U. parvum*.[208] Katz found no significant difference or trend in prevalence of either species in infants with or without bronchopulmonary disease, but there was a significantly greater likelihood of disease among infants whose endotracheal aspirates were positive for both species.[210] Additional studies must be performed to determine conclusively the extent to which any differential pathogenicity of *Ureaplasma* species occurs in clinical conditions known to be associated with these organisms, and under what circumstances. Availability of real-time PCR assays may prove to be very useful in determining their respective roles in disease.[211]

11.2. Pathogenesis and Immunity

Mycoplasmas are primarily mucosally associated organisms residing in the respiratory or urogenital tracts of their hosts in close association with epithelial cells. In some species invasion of host cells occurs and the organisms reside intracellularly. Such intracellular localization may contribute to the chronicity of infections and their ability to evade the host cell immune response.[5,155,212–214] Localization and attachment on host cell surfaces are important in the ability of mycoplasmas to colonize and subsequently produce pathological lesions, even if cellular internalization does not occur. In addition to *M. pneumoniae*, organisms such as *M. genitalium* also have a flask-shaped morphology and terminal attachment organelles and knowledge of their cytadherence processes is increasing. Factors involved with the attachment of *M. hominis* and *Ureaplasma* spp. to mucosal surfaces have not been extensively characterized. These organisms do not have the prominent attachment tips described in the other species mentioned above, but some investigation has been done in this area. A major adhesin protein, also known as the variable adherence-associated antigen (Vaa) may undergo antigenic variation and assist *M. hominis* in evasion of host immune defenses.[215–217] The Vaa antigen is expressed in vivo during chronic active arthritis associated with *M. hominis* infection and is highly immunogenic in the human host.[218]

Similar to what has been described for the Vaa antigen in *M. hominis*, the MB antigen of *Ureaplasma* spp.

undergoes a high rate of size variation in vitro and is size variable on invasive ureaplasma isolates.[215–217] The MB antigen contains serovar-specific and cross-reactive epitopes and is a predominant antigen recognized during human infections.[219]

Ureaplasmas are known to adhere to a variety of human cells including erythrocytes,[220] spermatozoa,[221] and urethral epithelial cells.[222] Ureaplasmas bind spontaneously to neutrophils and directly activate the first component of complement.[223,224] There may be several proteins involved in the cytadherence process of ureaplasmas, which has not yet been characterized in its entirety.[220,225] The receptors for ureaplasma adhesins are believed to be sialyl residues and/or sulfated compounds, similar to what has been observed for other mycoplasmas.

Arginine metabolism by *M. hominis* and urease activity in ureaplasmas have been suggested as potential virulence factors. Release of NH_3 in the urinary tract by ureaplasmas can cause elevation of urinary pH and precipitation of magnesium ammonium phosphate, also known as struvite. Immunoglobulin (Ig) A1 protease activity was first described in *Ureaplasma* spp. more than 20 years ago.[226] Since IgA is the predominant immunoglobulin secreted at mucosal surfaces, IgA proteases may facilitate colonization by microorganisms by degrading this important component of the mucosal immune system. However, Robertson et al.[226] emphasized that IgA1 protease may not be a significant virulence factor in ureaplasmas because they were able to detect its presence in men with NGU and with strains isolated from healthy persons. Attempts to identify the gene for IgA1 protease in the genome of *U. parvum* have not been successful, and there is speculation that the ureaplasma enzyme may have diverged so far from orthologues in other bacteria that they were unrecognizable or that it may have convergently evolved no recognizable similarity to other enzymes.[227] The presence of phospholipases A and C in *Ureaplasma* spp. has been suggested to be the means by which ureaplasmas may initiate preterm labor by liberating arachidonic acid and altering prostaglandin synthesis.[228–230] However, Glass and colleagues were unable to identify phospholipase activity in the serotype 3 ureaplasma strain for which the complete genome was sequenced and gave the same possible explanations as those for the apparent lack of IgA1 protease activity.[227]

An intact humoral immune system is very important to prevent infection and dissemination by genital mycoplasmas. This is quite evident by the well-known occurrences of these organisms, ureaplasmas in particular, in septic arthritis and persistent urethritis in persons with hypogammaglobulinemia and systemic infections in immunocompromised preterm neonates.[223,231,232]

11.3. Transmission

Ureaplasma spp. and *M. hominis* can be transmitted from person to person venereally, but they can also be transmitted vertically from mother to offspring by means of at least three different routes.[233] First, there can be an ascending intrauterine infection in which the organisms gain access to the amniotic sac where they multiply and are then passed into the fetal lung. This can occur early in pregnancy, even when fetal membranes are intact and infection can persist for several weeks. Fetal acquisition of these organisms can also occur through a hematogenous route through placental infection through involvement of the umbilical vessels. Finally, acquisition of these organisms by the neonate can occur through passage of an infected maternal birth canal with resultant colonization of the skin, mucosal membranes, and respiratory tract. Ureaplasmas can be isolated from the endotracheal secretions in up to 40% of newborn infants within 30 minutes to 24 hours after birth.[234–236]

Vertical transmission of *Ureaplasma* spp. has been reported to range from 18 to 88% and isolation rates vary inversely with gestational age, according to most studies.[232] Despite the likelihood that women who are colonized with genital mycoplasmas will transmit them to their offspring, the mere presence of these organisms in surface cultures of neonates is not evidence of pathogenicity. Although the presence of *Ureaplasma* spp. has been documented for long periods in the lower respiratory tract of preterm infants,[237] surface colonization of full-term infants tends to be transient and declines beyond 3 months of age.[238] Recolonization of the lower urogenital tract may occur following puberty and when sexual activity is initiated or if there is sexual abuse.[239] However, genital mycoplasmas may occasionally be isolated from the vagina of healthy prepubescent girls.[240]

11.4. Laboratory Detection

Although culture is considered the reference standard for detection of *M. hominis* and *Ureaplasma* spp., it is expensive, requires specialized media and expertise that are not widely available outside of larger medical centers, mycoplasma research or reference laboratories. Confirmed culture results can usually be available within 2–5 days, exclusive of specimen transport time and shipment if an off-site reference laboratory is used. Ureaplasmas can be positively identified to genus level by their colonial morphology and urease production. In contrast, mycoplasmal species such as *M. hominis* that produce fried egg colonies on A8 or SP4 agar may be presumptively identified based on growth rates, hydrolysis of arginine, and body site of origin, but definitive species identification requires additional tests which have histori-

cally included growth inhibition using homologous antisera, immunoblotting with monoclonal antibodies, colony epi-immunofluorescence, and, more recently, the PCR assay.[241]

Considerable attention has been given in recent years to the application of the PCR assay in primary detection of mycoplasmal and ureaplasmal perinatal infections. PCR is essential if fastidious, slow-growing organisms such as *M. genitalium* are sought and is also valuable in differentiating ureaplasmal species and serovars. Theoretical advantages of the PCR assay for detection of genital mycoplasmas include the fact that no viable organisms are necessary, its analytical sensitivity is much greater than culture, and results can be available in 1 day.

There has been interest in development of serological assays for detection of the host immune response to genital mycoplasmas. However, their ubiquity in the urogenital tracts of adults makes interpretation of antibody titers difficult, and the mere existence of antibodies alone cannot be considered significant in most circumstances. No assays for genital mycoplasmas have been standardized and made commercially available in the United States.

11.5. Treatment

Resistance to macrolides and lincosamides is variable according to species, with *M. hominis* being resistant to erythromycin but susceptible to clindamycin. For *Ureaplasma* spp., the reverse is true. Newer macrolides, azalides, and ketolides have shown activity at least as good as that of erythromycin against ureaplasmas. Tetracycline resistance has been well documented in recent years in both *M. hominis* and *Ureaplasma* spp., mediated by the *tetM* determinant which codes for a protein that binds to ribosomes, protecting them from the actions of these drugs. The extent to which tetracycline resistance occurs in genital mycoplasmas varies geographically and according to prior antimicrobial exposure in different populations, but may approach 40–50%. Information about tetracycline resistance in *M. genitalium* does not exist, but men with *M. genitalium*-positive NGU or women with cervicitis respond better to azithromycin than they do to a tetracycline, possibly because of the lower minimum inhibitory concentrations (MICs). There are very little outcome data documented in a controlled setting with microbiological studies to demonstrate efficacy of antimicrobial treatment of *M. genitalium* infections. Such information is needed in view of the growing importance of this mycoplasma in sexually transmitted disease. Other agents such as streptogramins, aminoglycosides, and chloramphenicol may show in vitro inhibitory activity against some species.

Extragenital infections, often in immunocompromised hosts, may be caused by multi-drug-resistant mycoplasmas and ureaplasmas, making guidance of chemotherapy by in vitro susceptibility tests important in this clinical setting. Eradication of infection under these circumstances can be extremely difficult, requiring prolonged therapy, even when the organisms are susceptible to the expected agents. This difficulty highlights the facts that mollicutes are inhibited but not killed by most commonly used bacteriostatic antimicrobial agents in concentrations achievable in vivo and that a functioning immune system plays an integral part in their eradication. Fluoroquinolones such as levofloxacin, moxifloxacin, and gatifloxacin tend to have greater in vitro activity than older drugs such as ciprofloxacin, but resistant strains have been reported.[242,243]

11.6. Unresolved Problems

Better techniques of detecting, identifying, and quantifying other human mycoplasmas are needed, and continuing research will facilitate optimization of methods to accurately determine antibiotic sensitivities in the laboratory. More research into the role of intracellular infections in mycoplasma diseases is required to provide a better understanding of pathogenesis for all human mycoplasma species.

CHAPTER 26

Healthcare-Acquired Bacterial Infections

Ebbing Lautenbach and Elias Abrutyn†

1. Introduction

The term "nosocomial" is derived from the combination of Greek *nosos* (disease) with *komein* (to take care of) as *nosokomeion* (hospital) and the Latin *nosocomium* (hospital). Nosocomial infections, then, are infections that develop and are recognized in patients and personnel in hospitals. These infections are not present or incubating on admission, with the exception that a nosocomial infection may be present on admission if it is directly related to or is the residual of a previous hospitalization. The reader may note that the title of this chapter has changed in a small but important way from the prior edition. We have acknowledged substantial changes in the field by revising the title from focusing on "nosocomial" infections to "healthcare-acquired" infections. As a greater number of individuals are cared for in non-acute-care health facilities (e.g., skilled nursing facilities, long-term care facilities) an understanding of infections in these settings is also vital. It has been increasingly recognized that infections which develop in such non-hospital, healthcare settings are very similar with regard to etiology and epidemiology to infections which occur in the hospital.[1] Although we will continue to use the term "nosocomial" to refer to infection occurring specifically in the hospital setting, the term "healthcare acquired" is increasingly accepted as a more inclusive term to describe infections that occur in the hospital and other healthcare settings. This reflects an identical change made several years ago by the Society for *Healthcare* Epidemiology of America (SHEA).

In hospitals alone, healthcare-acquired infections account for an estimated two million infections annually.[2] It is estimated that over 5% of all hospitalized patients fall victim to these infections each year in the United States.[3] Prevalence studies conducted in other countries with collaboration by the World Health Organization (WHO) have found rates from 3 to 20%, with a mean of 8.7 infections per 100 patients surveyed.[4] One-third to one-half of all nosocomial infections may be preventable.[5] Approximately 90% of reported healthcare-acquired infections are of bacterial etiology, with viral, fungal, protozoal, and other classes of microorganisms associated with a lesser but significant number of cases.[3] Healthcare infections exact a tremendous toll both in morbidity, mortality, and costs.[2] Hospital infections are estimated to account for 90,000 deaths and 4.5 billion dollars in excess healthcare costs annually.[2] Indeed, the number of nosocomial infections per 1,000 patient days has actually increased in the past two decades.[2] Several factors, including newer instruments and devices, more invasive procedures, sicker patient populations, stretched resources, and new patterns of antimicrobial resistance suggest that healthcare infections will continue to increase in the future.

2. Historical Background

Since the use of temples by the Egyptians, there have been documented attempts to provide special care, protection, and segregation for the sick. This gathering of the sick has frequently resulted in rapid transmission of infectious

agents among patients and personnel, and from unrecognized reservoirs within the institution with resultant high morbidity and mortality. Public recognition of hospitals as "pesthouses" was common up to modern times. The role of improved environmental sanitation and the importance of hygienic practices in reducing transmission and infection rates were recognized in the earliest medical traditions and were periodically rediscovered in the following centuries. The medical workers of the middle 1800s were especially productive. Florence Nightingale introduced broad hospital hygiene, transmission of puerperal fever was recognized by Semmelweis and controlled by hand washing with an antiseptic, and Lister introduced antisepsis to surgery. After Pasteur, the putrefaction associated with trauma and surgery was understood as related to transmissible microorganisms, and the importance of aseptic technique became well understood and practiced.[6,7]

The stunning early success of penicillin in controlling gram-positive coccal infections led to the misconception that antibiotics could control and eventually eradicate all infectious diseases. The carefully learned lessons of the past concerning aseptic technique were no longer given priority and support. The appearance of penicillin-resistant staphylococci in this milieu led to devastating hospital epidemics with these agents.[8] With the discovery of penicillinase-resistant penicillins, infections by resistant staphylococci became treatable, and associated epidemics decreased in importance. At the same time, the marketing of antibiotics with effectiveness against a broad spectrum of other microorganisms again led the unwary to discount the need for other control methods. However, the control of healthcare infections was not forthcoming. Indeed, recent years have witnessed the emergence and global spread of a wide variety of antimicrobial resistant pathogens such as methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, extended-spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae, and multidrug-resistant *Pseudomonas aeruginosa.*[9] These trends are all the more concerning given the association between antimicrobial resistant infection and negative clinical and economic outcomes,[10] as well as the recognized slowing of development of new antibacterials over the past decade.[11]

3. Methodology

3.1. Criteria for Infection

Widely accepted criteria for the identification and classification of nosocomial infection have been suggested by the Centers for Disease Control and Prevention (CDC).[12,13] These criteria satisfy both the need for scientific validity and the practical requirement for easy and uniform recognition necessary to discovery and enumeration. Examples are listed in Table 1. It is common practice to designate most bacterial infections that appear within the first 48 hour of hospital stay as community and not nosocomially acquired. In these criteria both infections from endogenous flora and infections transmitted from exogenous sources are included. Since microbiological sampling in clinical situations is neither routine nor uniform, the criteria are not dependent on the laboratory for data for fulfillment. Use of a clinical definition is mandated by studies indicating that from 16 to 59% of otherwise well-documented nosocomial infections are not supported by microbiological data in that no tests were submitted or tests were invalidated because of poor sampling, inadequate handling, or laboratory error.[4,14,15] Since both preventable and unavoidable infections are included in these criteria, care must be taken in assignment of causation and liability in the individual case.

3.2. Sources of Mortality Data

The usual hospital discharge and death certificate data rarely include comments on complications of nosocomial infection. Some individual studies[16,17] and an autopsy

Table 1. Sample Criteria for Determination of Nosocomial Infection[a]

Site	Clinical data	Laboratory data
Urinary tract	Suprapubic tenderness, dysuria, frequency, pyuria	Standard quantitative clean-catch urine culture[b]
Wound	Purulent drainage	Wound culture[b]
Respiratory tract	Physical signs, sputum change	X ray
	Purulent sputum	Sputum culture[b]
Intravenous	Purulent drainage, pain, erythema	Semiquantitative culture[b]
Gastrointestinal tract	Diarrhea	Stool culture[b]
		Toxin assay
Skin	Purulent drainage, physical signs	Culture[b]

[a]Modified from Garner et al.[12]
[b]Combinations of clinical data may be used to document infection in thr absence of laboratory microbiological isolation (see the text).

study[18] have been reported. Autopsy data may provide confirmation or documentation of unsuspected nosocomial infection through gross, microscopic, or microbiological cultural evidence. However, autopsy data are biased for patients dying in the hospital with the most severe or puzzling illnesses. These factors are associated with prolongation of hospital stay and other comorbid events predisposing to increased nosocomial infection. Since 1970, the National Healthcare Safety Network (NHSN) of the CDC (formerly known as the National Nosocomial Infections Surveillance [NNIS] system) has reported selected mortality and morbidity data from a volunteer group of hospitals in the United States, currently numbering approximately 300 hospitals.[3,9,19–22] These hospitals range in size from 100 beds to over 1,000 beds but are not geographically representative of all US hospitals. Furthermore, hospitals in the NHSN are more likely to represent larger, academic medical centers. While the system does not represent a probability sample of US hospitals, by stratifying hospitals by size and teaching characteristics, it has provided useful data. The NHSN data have tended to confirm the findings of the Study of Efficacy of Nosocomial Infection Control (SENIC) and other published reports.[23,24]

3.3. Sources of Morbidity Data

The uniform hospital discharge summary rarely indicates the complication of a nosocomial infection. In a study of risk factors important in nosocomial infection, Freeman and McGowan[25] found only 59% of nosocomial infections labeled with any diagnosis of infection as a primary or secondary discharge diagnosis and only 2% labeled as clearly indicating infection of a nosocomial origin. In a study conducted after the beginning of the new prospective payment systems in the United States, Massanari et al.[26] found that only 57% of nosocomial infections were properly recorded in the discharge abstracts of their university hospital. The retrospective audit of medical records to determine the frequency of nosocomial infection has been complicated by difficulties in completeness, illegibility, and inaccessibility. However, the results of a large, statistically complex, and well-controlled evaluation of the efficacy of nosocomial infection practice and control, using a measured and highly reliable retrospective medical record review methodology, have been reported by the CDC. The methodology and analysis of the SENIC project have been published in detail.[27,28]

The focal point of hospital infection control must be the patient. The most successful acquisition of data on nosocomial infection has been accomplished through nosocomial infection surveillance. Of critical importance is a specifically trained individual, the infection control practitioner or nurse epidemiologist.[29,30] This surveillance method actively acquires data from multiple laboratory[31,32] and clinical sources and uses it to fulfill criteria that define the presence of a nosocomial infection at a particular site. These traditional data sources have included concurrent review of the patient's clinical record, review of the medical nursing Kardex and other data sheets for evidence of infection, and coordinated supplement of these clinical sources with radiology reports, pharmacy data, and microbiological laboratory reports.[29,31–34] Advances in information technology have increasingly allowed a more systematic and streamlined approach to establishing baseline rates of infection and setting triggers for evaluation of a possible outbreak.[35,36]

Historically, nosocomial bacterial infections have not been reportable through any routine public health system. However, after years of discussion on both the federal and the state level, mandatory reporting of healthcare-associated infection rates has become a reality. Currently, mandatory reporting is required by four states, and legislation is pending in over 20 additional states.[37] Consumer demand for greater information regarding issues such as healthcare-associated infections has increased since the 1999 publication of the Institute of Medicine's "To Err is Human: Building a Safer Health System," which reported 98,000 deaths and $20 billion dollars spent per year in US hospitals associated with medical error.[38] Entities such as the Centers for Medicare and Medicaid Services (CMS), consumer groups, quality improvement and patient safety organizations, state and federal legislators, and the National Quality Forum are among those pursuing this issue on various levels. Professional organizations, including the Association For Professionals In Infection Control and Epidemiology (APIC), The Healthcare Infection Control Practices Advisory Committee (HICPAC) (a federal advisory committee that provides advice and guidance to the Department of Health and Human Services and CDC), and the Society of Healthcare Epidemiology of America (SHEA) have all issued statements and published reports relative to the issue of mandated public reporting.[39,40] To this point, the specific healthcare-associated outcomes to be reported are still being debated. The impact of public reporting has not to date been rigorously evaluated.

Another new trend in surveillance programs is "syndromic surveillance" which is used to track potential agents of bioterrorism and newly emerging diseases (e.g., severe acute respiratory syndrome).[41] These data would be routinely transmitted to the public health authorities as an "early warning" system for a bioterrorism event. The efficacy of such reporting systems has not been rigorously evaluated. Furthermore, the requisite components of such a reporting program remain unclear.

3.4. Surveillance

In addition to the NHSN and SENIC projects of the CDC, some statewide incidence and prevalence studies have been reported in the United States,[42] and the WHO and others have sponsored surveys in other regions of the world.[4,43–45]

3.4.1. Microbiological Surveys. Data routinely generated in the hospital microbiology laboratory have been widely used as a source of information of infections in hospitalized patients, and the increased use of diagnostic tests has been documented to increase the recognition of infectious diseases in acute-care institutions[23,46] The site of infection (e.g., urinary tract, blood, pulmonary, wound), patient location, causative organism(s), and antimicrobial susceptibility data can be determined and evaluated. Computerized data-processing methods have eased the collation and review of these data for recognition of clusters of infections at specific sites, in geographic locations, or of specific species or strains of bacteria.[31,32,47]

One of the most important activities performed by an institution's clinical microbiology laboratory is the reporting of cumulative and ongoing summaries of institutional patterns of antimicrobial susceptibilities, or antibiograms.[48–50] In addition to its critical role in identifying and monitoring patterns of emerging antimicrobial resistance,[35,51] the antibiogram is vital for making informed decisions regarding prescribing of empiric antimicrobial therapy.[52,53] The importance of optimizing empiric antimicrobial therapy has been highlighted by recent studies reconfirming a strong association between mortality and inadequate empiric antibiotic therapy.[54–56]

In 2002, the National Committee for Clinical Laboratory Standards (NCCLS) (now the Clinical and Laboratory Standards Institute, or CLSI) published guidelines to assist the preparation of antibiograms.[52] A study[57] conducted before these NCCLS guidelines became widely available noted that only 60% of surveyed US hospitals followed three of the basic guidelines previously proposed (i.e., compilation of an antibiogram, annual updating, and distribution to infection control staff and medical staff yearly).[50] More recently, a study of 65 academic institutions noted that 22% of centers update antibiograms at least every 6 months, while 78% update annually.[58] Although only 37% of centers report trends in susceptibilities over time, this practice was more common among teaching hospitals and in laboratories with a greater number of personnel.[58] Also, 63% of centers reported both inpatient and outpatient susceptibility data and 20% reported a separate antibiogram for different anatomic sites of culture.

In addition to informing empiric antimicrobial therapy, unit-specific susceptibility data may also permit more focused and prompt identification of changes in resistance to allow earlier intervention.[59,60] While fewer than 50% of laboratories report unit-specific antibiograms, this practice was significantly more common among teaching hospitals and laboratories with a greater number of personnel.[58] A recent study incorporated an assessment of unit-specific susceptibility rates into an intervention to improve empiric antimicrobial prescribing.[61]

Although 88% of centers exclude duplicate isolates when calculating susceptibility data, the time frame during which isolates are excluded was extremely variable.[58] Although it is well recognized that using different time cutoffs (e.g., 3, 7, 365 days) may result in important differences in reported susceptibility rates,[62–64] there has been little historical consensus on which criteria should be used. This lack of consistency makes interpretation of differences in susceptibility patterns across institutions more complex. The CLSI recommendations to include only the first isolate of a species per patient per analysis period (typically 1 year)[52] have been supported by recent studies as the simplest and most unambiguous approach.[65,66]

Although laboratory reports are a good source for initial case finding, the specificity of the survey of laboratory isolations is low. Isolation of an organism does not separate community acquired from nosocomial infection and does not specify causation in differentiating commensal from infecting bacteria without additional clinical information. Furthermore, the sensitivity of this system is dependent on the uniformity of the collection of specimens and of culturing practices, features of laboratory practice that are known to vary widely. However, when laboratory data are combined with information from other databases in a highly computerized hospital information system, sensitivities for the identification of nosocomial infection were reported that were equal to or exceeded other methods and at an efficiency that required approximately one-third of personnel devoted to routine surveillance.[35]

Routine microbiological surveys of hospitalized patients or the hospital environment are unnecessary and economically unjustifiable. In the absence of epidemic or outbreak situations, there is no evidence that this type of routine sampling has contributed significantly to detection or prevention of nosocomial infections. In epidemic situations, environmental cultures should be considered only if epidemiological evidence indicates an environmental source for the organism. The incidence of nosocomial infection has not been related to levels of microbial contamination of air, surfaces, or fomites, and meaningful standards for permissible levels of such contamination do not exist.[67–70]

The spread of nosocomial organisms in endemic and most epidemic situations is associated with contact transmission via personnel hands or due to contamination of

an item that should be sterile. Therefore, the role of environmental microbiological sampling is currently reduced to (1) assisting in epidemic investigation in selected circumstances, (2) evaluation of new techniques, (3) serving as an important adjunct to educational programs in the support of nosocomial infection control, and (4) quality control routine monitoring of sterilization, dialysis fluids, infant formula prepared in the hospital, and samples of certain disinfected equipment.

3.4.2. Prevalence Surveys. A prevalence survey of healthcare-associated infections based on application of uniform criteria to all patients in an institution during a single day or time period has provided a rapid, inexpensive, and corroborative means of assessing nosocomial infection risk within an institution. Periodic prevalence data have been used as an evaluative tool in infection control programs,[25] as an estimator of risk across a wide variety of institutions,[14,71] including programs of the WHO,[4] and as an important quality control feature of other data collection methods.[30] As with all prevalence studies, bias inherent in sampling of a single day's experience as an indicator of typical risk must be recognized. In particulate, because new and existing infections are counted, the rates obtained from prevalence surveys are usually higher than incidence rates.

3.4.3. Surveillance Studies. Currently the most widely propagated surveillance method for the collection of nosocomial infection data employs a trained individual, a nurse epidemiologist, or infection control practitioner.[34,72,73] This individual concurrently provides a coordinated review of each patient's clinical and laboratory data, recording those instances that satisfy the standard criteria for identification of a nosocomial infection. These data are summarized on a periodic (monthly, quarterly, yearly) basis, collated, analyzed, and reported to a specific multidisciplinary committee within the hospital and to certain key hospital personnel.[29,30] The importance of the unbiased collection of these data by a trained professional has been repeatedly documented by studies indicating reduced efficiency and accuracy of reporting by other methods[74,75] and by the results of the SENIC project.[28]

The institutional infection control committee recommends appropriate control measures, based on the priorities of risk indicated by the data previously collected and evaluated.[76–78] The infection control committee plays a vital role in ensuring patient safety through the prevention and control of infections in a healthcare facility. This committee is a mechanism for the infection control program to report activities including statistics, outbreaks, and proactive control measures. The infection control committee also drafts and disseminates policies and procedures on infection surveillance, prevention, control, and education. Infection control committees vary in that some serve single healthcare facilities (hospitals or long-term care facilities), while others are regional committees.[76–78]

The continuous collection of nosocomial infection data allows concurrent evaluation of these control efforts. This form of nosocomial infection data collection, evaluation, and recommendation has been termed "a nosocomial infection surveillance and control program."[79] This format has been widely promoted and supported by the Hospital Infections Program of the CDC since the first reports of its successful use in 1969.[30]

Three demonstration projects by the CDC have investigated this format as the prime method to investigate and control nosocomial infections in the US hospitals. The Comprehensive Hospital Infection Project (CHIP) collected intensive surveillance data in nine community hospitals between January 1970 and June 1973, using definitions and methods suggested by the CDC.[30,79] At 4-month intervals, CDC medical epidemiologists conducted onsite prevalence surveys to evaluate surveillance efficiency.

The NHSN (formerly NNIS) system, while not statistically representative of all US hospitals, does contain community, community teaching, state, local, and university hospitals.[9] Large hospitals with more than 500 beds are overrepresented and small hospitals with fewer than 200 beds are under-represented in the system.[22] Each hospital is required to have an active infection control program, but until recently there was little attempt to evaluate or control the quality of the submitted data. Recently the requirements for membership in the system have been increased, criteria for infection have been improved and standardized, and reliable electronic submission of data has been required in an attempt to improve both the scope and the quality of the information submitted. Data reported by the NHSN system are reviewed in Section 5.

In 1974, the CDC initiated the SENIC project, which thereafter collected data in 338 randomly selected US hospitals. The objectives of this study were to estimate the magnitude of the nosocomial infection problem in US hospitals, to describe the extent of hospitals' infection surveillance and control programs, and to evaluate the efficacy and effectiveness of these programs in reducing nosocomial infection risks. The extensive and complex methodology of the study was reported in 1980, and the results and evaluation were reported in 1985.[27,28,44] The results indicate that in the one-third of hospitals supporting the lowest levels of surveillance and control programs, nosocomial infections had increased in the period between 1970 and 1975–1976 by 18%. In the same time period in the 0.5% of hospitals with the highest levels of surveillance and control, nosocomial infections had decreased by approximately one-third.

Of the approximately one-third of infections estimated to be reduced by the most intensive surveillance and control

programs, surgical wound infections were found to be the risk most amenable to control and the problem that demonstrated the greatest risk of both increased cost and length of stay. Bacteremias and urinary tract infections were intermediate in reduction by CDC methods; pneumonias proved to be the most refractory, and nosocomial medical pneumonias were not being significantly reduced.

The most effective programs conducted high-level balanced surveillance and control activities, had a trained hospital epidemiologist, supported an infection control practitioner for each 250 beds, and had a system of reporting wound infection rates to individual surgeons. Unfortunately, it was estimated that only 6% of nosocomial infections were being prevented at the end of the study. A follow-up study in 1983 indicated that this figure had risen to 9%, or approximately 28% of the potential estimated to be possible by current methods.[80] Some question the applicability of the findings (particularly the adequacy of one infection control practitioner for 250 beds) to hospitals today since the amount and complexity of the work of the infection control practitioner has increased, the care of patients in the healthcare setting has become more complex, and the severity of illness of the hospitalized patient population has continued to increase.[78]

3.5. Laboratory Diagnosis

Over the past several decades, the clinical microbiology laboratory has assumed an ever increasing critical role for ongoing management and control of healthcare-associated infectious diseases. Surveillance from the laboratory can measure institution-wide occurrences from a single, central data collection point. Although the optimal approach for managing healthcare-associated infections is to gather the broadest surveillance data, a primary obstacle to achieving this goal has been that manually attempting universal surveillance is very resource intensive and the amount of data collected is overwhelming, even with any traditional computer analysis.[81] It has been estimated that 20th century approaches to analyzing laboratory data will detect not more than two-thirds of nosocomial infections.[82] However, many now believe that the use of laboratory data will prove the most cost-effective, comprehensive surveillance approach once sufficient analytical tools are available.[83]

A 1998 consensus report set the current standard for required microbiology laboratory services as part of a comprehensive infection control program.[78] The final report indicated that the necessary contribution from the laboratory included surveillance (e.g., providing for a systematic observance and measurement of disease) as well as molecular typing of microbial pathogens.[78] Present and future needs for laboratory-based surveillance will require reliable detection of new pathogens that emerge as causes of important healthcare-associated infections, which implies accurate identification of microbial organisms; recognition of new or emerging antimicrobial agent resistance; and participation in active surveillance for outbreaks (i.e., prospective assessment of colonization with organisms of interest), including preparation of specialized growth media as well as molecular typing.[84] This evolving role dictates the need for a strong collaboration between the hospital epidemiologist and the clinical microbiologist.[85]

3.5.1. Isolation and Identification of Organisms. Standard, reliable laboratory identification of bacteria in clinical samples from suspected nosocomial infection is important epidemiologically to link sources of transmitted microorganisms. The most important steps in assuring the validity of this process begin at the bedside with the collection of body fluids for testing. Inappropriate collection of specimens magnifies the usual difficulties in differentiation of normal flora of the body from truly infecting microbes. For example, pulmonary secretions collected through the oropharynx may be heavily contaminated by commensal oropharyngeal bacteria.[86] Similarly, urine specimens may become contaminated when not obtained by "clean-catch, midstream voiding" or by direct bladder catheterization. Cultures from other normally sterile sites must be obtained only after proper preparation of the location to be sampled for results of cultures to be meaningful.

A delay in transport to the laboratory or transport under inappropriate environmental conditions or in a hostile medium may hinder identification of important infecting bacteria. Urine cultures held at room temperature may allow bacteria therein to multiply beyond the usual criteria for identification of a nosocomial urinary tract infection. A collection of anaerobic organisms in cold medium and carriage at ambient oxygen levels may inhibit subsequent growth to an extent that thwarts laboratory rescue and identification.

Many laboratory findings suggest improper collection or transport of specimens. Isolation of skin flora, such as diphtheroids or coagulase-negative staphylococci, from normally sterile sites suggests contamination at the time of collection. The recovery of three or more species of bacteria from urine specimens suggests unsatisfactory technique in collection or handling. The inability to recover anaerobes seen on Gram's stain suggests inappropriate transport of specimens or culturing technique. Negative cultures for *Mycobacterium tuberculosis* in patients at high risk may suggest inappropriate sputum collection. Delayed receipt of sputum specimens diminishes the laboratory's ability to isolate pneumococci from specimens due to overgrowth of the organism by normal oropharyngeal flora. If such

inappropriate sampling, mishandling, and delay are not recognized by the laboratory, they may result in the unintentional misreporting of no organisms or of microbes of no clinical significance.

3.5.2. Evaluation of Specimens: Initial Screening. The laboratory specialist is guided by the description of the site of sampling and other clinical information forwarded by the requesting physician. The absence of such information accompanying the specimen may lead to serious mishandling or delay in identification in the laboratory. Recording the time of arrival of the specimen in the laboratory as compared to time of collection may be used to determine delays in transport that will result in an inability to culture fastidious organisms. Specimens received in improper collection containers can also be noted at the time of initial evaluation. In these instances, repeat cultures should be requested.

Assessment of specimens at the time they are received in the laboratory by direct microscopic examination is important in evaluating the acceptability of a specimen for further diagnostic testing. The laboratory use of differential cellular characteristics of sputum and saliva has been helpful in clarifying the source of specimens and their acceptability for diagnostic testing.[87] Specimens containing more than ten squamous epithelial cells per low-power ($\times 10$) field suggest contamination with oropharyngeal flora. Material from wounds that do not show polymorphonuclear leukocytes is also unlikely to yield a causative organism when cultured. Smears and other recently developed rapid diagnostic tests that evaluate antigen or antibody detection are of enormous importance in patient management. Smears are also important for detecting organisms of epidemiological significance, such as *Haemophilus, Legionella*, or *M. tuberculosis*, that may not be reflected by culture or that may take long periods of time to grow.

Sufficient sophistication in the laboratory is necessary to assure identification to the species level of the common bacteria endemic to the institution. Standard methods are available in many manuals and texts.[88] Reference bacteriology should be conveniently available to assist in the identification of more unusual microbes. The degree to which organisms are identified to the species level can also have epidemiological importance. For example, a report of *Pseudomonas* species fails to distinguish between a variety of related organisms, such as *P. aeruginosa* and *P. cepacia*, which have different reservoirs and modes of transmission. Identifying organisms as *P. cepacia* has etiologic significance, since *P. cepacia* are associated with outbreaks or pseudoepidemics caused by contaminated water or solutions.[89]

3.5.3. In Vitro Susceptibility Testing. Testing of the sensitivity of isolates to a spectrum of antibiotics is a commonly used clinical and epidemiological tool. Standardized Kirby–Bauer disk diffusion testing or the more exacting microdilution minimum inhibitory concentration (MIC) tests provide useful information regarding the susceptibility of the bacterial isolate.[88] Disk diffusion testing is performed by measuring the zone of inhibition around an antibiotic-impregnated disk. Zone diameter are interpreted in signifying susceptible, intermediate, or resistant organisms. Microdilution testing provides a quantitative measurement of the MIC, which is defined as the lowest concentration of antibiotic that results in inhibition of growth of the organism.

The results of susceptibility studies provide guidance both to the clinician for appropriate therapy and to the epidemiologist as an inexpensive screen for possible common identity of speciated organisms.[46] However, antibiotic sensitivity does not ensure similarity of speciated organisms; organisms may have similar antibiotic resistances and yet be epidemiologically unrelated.[90–92]

3.5.4. Quality Control in the Laboratory. Quality control is essential to effective microbiology laboratory and infection control programs. Pseudoepidemics due to contamination of specimens in the laboratory by automated laboratory equipment or other routes have occurred.[93,94] New procedures in the laboratory related to susceptibility testing, new culture techniques, or new ways of reporting results or of naming organisms can also lead to confusion, pseudoepidemics, or lack of recognition of related organisms.

3.5.5. Special Studies for Examining the Relatedness of Isolates. Molecular typing methods have become increasingly powerful tools for epidemiologic investigations of nosocomial infections[95] (see Chapter 3). When used as adjuncts to classical epidemiologic studies, these methods can greatly facilitate the investigation of nosocomial infections and outbreaks. A major caveat is that results of molecular typing should never be interpreted in the absence of data from sound clinical epidemiologic studies. Although molecular studies can help to prove or disprove epidemiologic hypothesis, when used inappropriately, incorrect conclusions may be drawn.

The goal of strain typing in the investigation of outbreaks is to provide laboratory evidence that epidemiologically related isolates are also genetically related and therefore are the same strain, presumably transmitted by a common source of exposure or from patient to patient.[96] Molecular techniques have been increasingly employed to detect slow-growing or fastidious organisms such as *Bartonella henselae* and *Mycobacterium tuberculosis*. A more recent use has been the rapid detection of organisms carrying antibiotic resistance genes such as those that encode for methicillin and vancomycin resistance. These techniques offer advantages in infection control and more timely appropriate treatment for patients.[97]

3.5.5.1. Plasmid Restriction Enzyme Analysis (REA). Molecular methods that analyze bacterial plasmid DNA increasingly have been used to determine relatedness of isolates. Diverse species of gram-negative and gram-positive bacteria have been studied using this approach.[91,98,99] Bacterial plasmids are extrachromosomal DNA elements present in most bacteria. Plasmids are extracted from bacteria by cell lysis and separated by agarose gel electrophoresis. In restriction enzyme analysis (REA), restriction endonucleases, enzymes that digest (cleave) DNA at particular sequences, are used to cleave the plasmids prior to separating them on a gel and comparing the numbers and sizes of the fragments. Plasmid REA is the simplest of the DNA-based methods and relatively inexpensive. It is limited by the fact that plasmids can be spread to multiple species ("plasmid outbreak"), lost spontaneously, or altered by mobile genetic elements that they frequently carry.

3.5.5.2. Chromosomal Restriction Enzyme Analysis (REA). The chromosome is a stable marker of strain identity. This method allows a larger amount of genetic material to be compared than with plasmid typing. The technique has been particularly useful for bacteria that lacks plasmids. The extracted chromosomal DNA is cleaved with a restriction enzyme, and the resulting linear fragments of DNA are separated by agarose gel electrophoresis. Different strains of the same bacterial species have different REA profiles because of variations in DNA sequences that alter the frequency and distribution of restriction sites. The advantage of this technique is that all isolates are typeable by REA. The disadvantage, however, is the difficulty in interpreting complex profiles that may contain hundreds of unresolved and overlapping bands. REA patterns may also be confounded by the presence of contaminating plasmids.

3.5.5.3. DNA–DNA Hybridization. The complex banding patterns generated with chromosomal DNA restriction enzyme analysis are more easily interpreted when a few discrete DNA fragments are highlighted by hybridizing the chromosomal DNA with a DNA probe that recognizes a specific gene or region of a gene that is present on a few fragments. Several bacteria have been typed with this technique, including *M. tuberculosis*. Ribotyping is another chromosomal typing technique that uses ribosomal RNA as the probe. This technique is based on the finding that the genes that encode subunits of ribosomal RNA are conserved between species and scattered throughout the chromosome of most bacteria.

3.5.5.4. Pulsed-Field Gel Electrophoresis. This technique has proven to be an excellent typing method that has been successfully used for a wide variety of bacterial species. Although special equipment is required to perform this technique, it is becoming the method of choice for typing many bacteria.[100] Guidelines with criteria for strain typing with PFGE have been published.[96] Pulsed-field gel electrophoresis allows for the separation of large genomic DNA molecules generated by rare cutting restriction enzymes. In contrast to REA, the restriction enzymes used in PFGE have fewer recognition sites in the bacterial chromosomal DNA, yielding a smaller number (10–30) of restriction fragments. The large DNA fragments are separated on agarose gels that are subjected to alternating electric fields. Relatively clear patterns that can be compared are generated in this manner.

3.5.5.5. Polymerase Chain Reaction (PCR). This powerful technique has been adapted for use as a typing tool for epidemiologic investigations. With it, very small amounts or sequences of DNA can be detected by amplifying specific nucleotide sequences and increasing the number of DNA copies. This technique permits the characterization of a "molecular fingerprint" for each organism based on its unique sequences of DNA (or RNA). The technique is much more sensitive than DNA–DNA hybridization with a specific DNA probe. Compared to other methods, PCR offers the advantage of speed (minutes to hours) and is unrivaled in sensitivity.[101] The high sensitivity of PCR can lead to its greatest limitation, in that false-positive results can occur due to amplification of contaminating DNA that may be present in a sample. Therefore, PCR should be performed only by personnel trained for the technique in a laboratory specifically set up for the procedure, and negative controls must always be used.

4. Biological Characteristics of Nosocomial Organisms

The relative frequency of the species of bacteria causing healthcare-acquired infections has changed remarkably over the past 30 years.[3,9,21,102] Changes in sensitivity to antimicrobial agents have also been observed.[9] These changes in the development and persistence of resistant strains have likely been related to the selective pressure of the widespread use and misuse of antimicrobial agents.[103] These patterns appear to be an extremely important phenomenon in local institutions and geographical areas,[104] as well as on a national level.[49,105] The biological characteristics important in these resistance changes may be generalized to (1) the ability of bacteria to survive in the normal flora of the host, (2) the ability of bacteria to survive in the animate and inanimate environments of the healthcare facility, and (3) the ability of the bacteria to survive antimicrobial stress through acquired resistance.

4.1. Infecting Normal Flora

Bacteria that normally reside as commensals on the internal and external surfaces of the host have been increasingly recognized as causal in nosocomial infections.[106–112] In hospitalized patients, the normal pharyngeal and intestinal flora may be displaced by antibiotic-resistant strains. The changes brought about by modification in the host by disease and by treatment factors occur within a few days of hospitalization. These bacteria then can serve as sources for infection in the colonized patient or are transmitted between patients nosocomially.[113] The ability of bacteria to infect is determined by the product of their number and virulence and inversely related to the quality and quantity of host defenses. In this context the term *normal flora* has become suspect in the recognition of the fact that virtually any microorganism that appears in the host may be invasive and disease causing, given a sufficiently impaired patient.[113,114]

4.2. Antimicrobial Resistance

The emergence of antimicrobial resistance has threatened to render the existing antibiotic arsenal useless. Both the number of organisms exhibiting resistance and the mechanisms of resistance have increased sharply in recent years.[115] Infections due to antibiotic-resistant bacteria are associated with increased morbidity, mortality, and hospital costs.[116,117] Of note, expenditures due to antimicrobial resistance in the United States in 1995 were estimated to be $4 billion.[118] Increasing antimicrobial resistance is of great concern not only because the agents available to treat these resistant infections are limited but also because the treatment of infectious diseases relies heavily on empiric therapy. Empiricism has become increasingly difficult as the susceptibility patterns of common pathogens become more complicated and unpredictable. Furthermore, development of new antimicrobials has slowed significantly over the past 10 years.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Many studies from the United States and other countries have estimated the magnitude of nosocomial infection by a variety of methods. Examples of data from those that have used criteria for infection compatible with those developed and used by the CDC are presented in Table 2. Based on these criteria, these studies routinely include in their totals infections for which no cultures were done or for which no pathogens were isolated. The infections identified by clinical criteria alone make up from 16 to 59% of the data.[4,9,14,27]

Historically, the nosocomial infection "rate," more precisely a ratio, has commonly been calculated as a cumulative incidence, expressed as the number of nosocomial infections per 100, 1,000, or 10,000 *patient discharges*[30,79] A preferred ratio expressed in infection per 1,000 or 10,000 *patient days of risk*[25,119–122] has been used in reports of incidence data. This incidence rate (or incidence density) is defined as the number of new infections in a specified quantity of person–time of observation among individuals at risk. This latter rate is especially valuable in comparing nosocomial risk in institutions or services with widely varying length of stay. Although this ratio accounts for length of stay, it does not take into account the use of invasive devices, which are a major risk factor for specific nosocomial infections, e.g., intravascular catheters for bloodstream infections, urinary catheters for urinary tract infections, and ventilators for pneumonias.[123] Risk-factor-specific infection rates have been developed to account for exposure to these extrinsic and powerful risk factors. The rate is expressed as the number of device-associated infections for a site per 1,000 device days of risk. These rates are considered more appropriate for interhospital as well as intrahospital comparison than the overall nosocomial infection rate, as they partially control for length of stay and device use.

5.1.1. Mortality Data. Estimates of the role of nosocomial infection in mortality have varied widely. CDC–NNIS data estimated that 0.7% of nosocomial infections directly caused death and 3.1% of infections contributed to death.[3] In a retrospective study of 1,000 autopsies from a university hospital, in which 75% of patients who died were examined, Daschner et al.[18] found an overall nosocomial infection rate of 13.7%. In those individuals with nosocomial infection, 54% of the deaths resulted directly from infection. In a retrospective study of 100 consecutive deaths at each of two hospitals, Gross et al.[17] found death causally related to nosocomial infections in 2.5% and contributing in 3.4% of patients without underlying terminal illness. In those with terminal illness on admission, the rates increase to 9.2 and 10.9%, respectively. In hospitals alone, healthcare-associated infections account for an estimated 2 million infections, 90,000 deaths, and $4.5 billion in excess healthcare costs annually.[2] Given that the severity of illness of the hospitalized patient population has continued to increase,[78] it is expected that the impact of healthcare-associated infections will continue to increase in the future.

5.1.2. Prevalence Studies. Prevalence studies conducted in US acute-care hospitals, using CDC–NNIS-compatible criteria, have reported rates ranging from 7.2% in small, predominantly rural hospitals[14] to as high as 15.5%

Table 2. Prevalence and Incidence Rates of Nosocomial Infection[a]

Location	Years	Type of hospitals	Type of study	Rate (%)
United States				
Virginia	1972–1975[24]	University	Incidence	6.7
Utah	1972–1973[14]	Community <75 beds	Prevalence	7.2
	1977[71]	Community <75 beds	Incidence	2.0
West Germany	1976[18]	University	Incidence	6.6
United Kingdom	1980[334]	Community	Autopsy	13.7
			Prevalence	9.2
Israel	1975–1976[335]	University	Incidence	12.2
United States	1984[3]	Mixed NNIS-CDC[b]	Incidence	3.4
		Community NNIS-CDC[b]	Incidence	2.2
		University NNIS-CDC[b]	Incidence	4.1
WHO	1983–1985[4]	Mixed	Prevalence	9.9

[a]Infections per 100 hospital discharges.
[b]NNIS, National Nosocomial Infections Study.

in a large, metropolitan teaching hospital[102] (Table 2). A WHO cooperative hospital infection prevalence survey was carried out between 1983 and 1985 in 55 hospitals in 14 countries in the four regions of Europe, Mediterranean, Southeast Asia, and western Pacific.[4] Results reported from 47 hospitals and 28,861 patients showed a mean prevalence rate of 8.7% with regional means from 7.7 to 11.8% and individual institutional rates from 3.0 to 20.7%. Since multiple infections were not recorded, an adjusted mean of 9.9% for the total was estimated, suggesting that approximately one patient in ten in these hospitals was infected while under care.

Prevalence data reported for infections from extended-care facilities have ranged from 2 to 18%.[124–127] These studies have used varying criteria and methodology, making comparisons difficult. Studies in these institutions require special criteria and methods different from those commonly used in acute-care institutions, since the availability of laboratory data, the extent of daily medical record documentation, and the resources available for data collection and analysis are less in this setting. Standard definitions for healthcare-acquired infections for use in extended-care facilities have been proposed.[128]

The definitions for healthcare-acquired infections in extended-care facilities[128] have also been applied to the home healthcare population.[129] Over 20% of patients were found to have an infection on the day of the survey; 5% of those infections had occurred during the course of home health care.[129]

5.1.3. Incidence Studies. Using definitions and methodologies outlined by the CDC for NNIS, a large number of incidence studies have been reported (Table 2). As noted previously, rates of nosocomial infections are most useful when reported for specifically defined populations at risk (e.g., bloodstream infections in patients with indwelling central venous catheters). In the most recent (2004) NNIS report, the rate of catheter-associated urinary tract infection (i.e., number of urinary catheter-associated urinary tract infections per 1,000 urinary catheter days) was 3.9 (10th–90th percentile = 1.3–7.9). This rate ranged from 3.0 in cardiothoracic ICUs to 6.7 in neurosurgical ICUs.[9] The rate of central venous catheter-associated bloodstream infections (i.e., number of central venous catheter-associated bloodstream infections per 1,000 catheter days) was 4.0 (10th–90th percentile = 1.7–7.6). This rate ranged from 2.7 in cardiothoracic ICUs to 7.4 in trauma ICUs.[9] Finally, the rate of ventilator-associated pneumonia (i.e., number of pneumonias per 1,000 ventilator days) was 5.4 (10th–90th percentile = 1.2–7.2). This rate ranged from 2.9 in pediatric ICUs to 15.2 in trauma ICUs.[9]

A 2006 study which investigated device-associated infections in 55 ICUs of 46 hospitals in eight countries noted all rates to be substantially higher than those previously reported in the United States.[130] The rate of catheter-associated urinary tract infection (i.e., number of urinary catheter-associated urinary tract infections per 1,000 urinary catheter days) was 8.9 (10th–90th percentilex = 1.7–12.8). The rate of central venous catheter-associated bloodstream infections (i.e., number of central venous catheter-associated bloodstream infections per 1,000 catheter days) was 12.5 (10th–90th percentile = 7.8–18.5). Finally, the rate of ventilator-associated pneumonia (i.e., number of pneumonias per 1,000 ventilator days) was 24.1 (10th–90th percentile = 10.0–52.7).[130]

5.1.4. Site-Pathogen Analysis. The site of nosocomial infection and the pathogen(s) reported as responsible

for them vary in incidence, relative frequency, morbidity, and mortality. The distribution of nosocomial infections by site varies by hospital service. This variation probably reflects differences in exposure to devices and procedures. CDC–NNIS data from 1996[131] report the site distribution of nosocomial infection based on the hospital-wide surveillance component as follows: urinary tract infection (27.2%), surgical site infection (18.7%), pneumonia (17.3%), primary bloodstream infection (15.8%), and other (21%). Site-pathogen data from the NNIS for the period 1990–1992 are given in Table 3.

5.1.4.1. Urinary Tract Infections. Infections of the urinary tract are consistently reported in Europe and the United States as comprising 30–45% of the total infections identified and are the most common cause of nosocomial infections.[4,24,105,132] Urinary tract infections are also the most common cause of infections in the long-term care facilities. The prevalence of UTI without indwelling catheters can be as high as 50% in women and 40% in men.[133] Over 60% of these infections are caused by gram-negative bacilli, with *Escherichia coli* causing approximately one quarter.[134] Enterococci and *P. aeruginosa* appear next in frequency in hospitals in the United States, while *Proteus* species are more frequently reported in the WHO data and in extended-care facilities in the United States. Secondary bacteremia appears in approximately 1% of individuals with nosocomial urinary tract infections, with the urinary tract being the second most common cause of healthcare-associated bloodstream infection. Increased morbidity and mortality independent of the infection's progression to sepsis have been noted in patients with healthcare-associated UTI.[135,136]

5.1.4.2. Surgical Site Infections. Surgical site infections are the second most common healthcare-associated infection in the United States accounting for approximately 20% of all nosocomial infections.[137] In some developing areas, up to one third of reported infections have involved surgical sites.[4] Approximately 500,000 SSIs occur annually, accounting for 3.7 million excess hospital days and over 1.6 billion dollars in excess hospital costs.[138] In hospitals participating in the NNIS program, 0.62 to 1.9% of patients with SSIs died from these infections.[105] Following a classification system for wounds (clean, clean contaminated, contaminated, or dirty) used in The National Research Council Study reported in 1964,[139] recent studies usually have reported risk of infection in postoperative surgical sites based on the probability of wound contamination during surgery. Surgical site infections usually arise as a result of intraoperative seeding of exogenous bacteria or as a result of dissemination of endogenous bacteria to the operative site. A number of factors determine the risk of surgical site infection, including the degree of microbiological contamination during the procedure, the duration of the procedure, and the patient's intrinsic risk. In order to use surgical site infection rates for comparative purposes, the rates should be adjusted

Table 3. Relative Frequency of Nosocomial Infection by Site and Selected Pathogens[a]

	Site (% of isolates)					
Pathogen	UTI	SSI	Pneumonia	BSI	Other	Percent
E. coli	25	8	4	8	4	12
S. aureus	2	19	20	16	17	12
Coagulase-negative staphylococci	4	14	2	31	14	11
Enterococci	16	12	2	9	5	10
P. aeruginosa	11	8	16	3	6	9
Candida spp.	10	4	6	8	6	7
Enterobacter spp.	5	7	11	4	4	6
Klebsiella spp.	8	4	10	5	4	6
Gram-positive anaerobes	0	1	0	1	19	4
Proteus mirabilis	5	3	2	1	2	3
Other *Streptococcus* spp.	1	3	1	4	2	2
Other fungi	3	0	1	1	1	2
Acinetobacter spp.	1	1	4	2	1	1
Serratia marcescens	1	1	3	1	1	1
Citrobacter spp.	2	1	1	1	1	1
Group B *Streptococcus*	1	1	1	2	1	1
Haemophilus influenzae	0	0	5	0	2	1
Other non-*Enterobacteriaceae* aerobes	0	1	4	1	2	1
Number of isolates	25,371	11,724	8,891	9,444	14,981	70,411

[a] Adapted from Emori and Gaynes[129]; NNIS 1990–1992.
No other pathogens accounted for more than 2% of isolates at any site.

for these risks. The NNIS has developed a surgical site infection risk index, which takes into account the patient's wound class, the American Society of Anesthesiology score, and the duration of the procedure.[123] In order to make comparisons between institutions or surgeons, surgical site infection rates should be stratified by risk categories.[140,141]

Staphylococcus aureus remains the most common isolate from wound infections,[4,21,105] although coagulase-negative staphylococci, enterococci, and gram-negative organisms have also been increasing in importance in recent years.[21] Only two-thirds of inpatients' surgical wounds and even fewer outpatients' wounds are cultured, despite clinical evidence for a surgical site infection.[142] It is important to note that a wound culture that grows a bacteria does not prove that a patient has a surgical site infection. Instead, the organisms may be colonizing the wound. Furthermore, a negative culture does not eliminate the diagnosis of a surgical site infection. For example, wound cellulitis often yields negative cultures and organisms such as *M. tuberculosis* are not detected by routine culture methods.

5.1.4.3. Respiratory Infections (i.e., Pneumonia). Nosocomial pneumonia is generally defined as pneumonia occurring 48 hours or more after hospital admission. Ventilator-associated pneumonia is a sub-group of nsoocomial pneumonia and is defined as pneumonia developing more than 48–72 hours after initiation of mechanical ventilation. Most published work on nosocomial pneumonia involves patients in intensive-care units, and in particular, mechanically ventilated patients who develop ventilator-associated pneumonia. Respiratory infections in the form of pneumonias make up a approximately 15–25% of all nosocomial infections. *P. aeruginosa* and *S. aureus* are the two most commonly reported pathogens.[21] Other gram-negative agents are also causal agents reported with significant frequency in most studies.[4,21,143] Published estimates suggest rates of 5–10 cases per 1,000 hospitalizations.[144,145] Patients with endotracheal tubes have rates that are up to 20-fold higher than patients without endotracheal tubes. A recent report showed that nearly 1 in 10 patients who required mechanical ventilation for more than 24 hours developed ventilator-associated pneumonia.[146] The chance of infection increases with duration of mechanical ventilation.

Nosocomial pneumonias are the leading cause of death from nosocomial infection. Secondary bacteremias are occur more frequently in nosocomial pneumonia than in either urinary or wound infections, and case-fatality rates for nosocomial pneumonias are only exceeded by those for bacteremia. Although the precise attributable mortality of nosocomial pneumonia is difficult to discern, some studies have suggested attributable mortality rates for ventilator-associated pneumonia as high as 30%. Multiple studies have shown that nosocomial pneumonia increases hospital length of stay by an average of 7–10 days. In patients with ventilator-associated pneumonia (VAP), the duration of both mechanical ventilation and ICU stay is increased, and the attributable cost of VAP at one tertiary-care medical center was nearly $12,000.[147] In another large epidemiologic study, patients who developed VAP had a mean increase of over $40,000 in hospital charges.[146]

5.1.4.4. Nosocomial Bloodstream Infection. Nosocomial bloodstream infections are one of the predominant causes of morbidity and mortality in the United States.[148] Central venous catheters are the source of most primary bloodstream infections,[149] leading to approximately 250,000–500,000 hospital-acquired bloodstream infections in the United States annually.[150–152] Since the 1980s, the incidence of primary healthcare-associated bloodstream infections has been rising steadily,[153] and the majority of these are related to the use of intravascular devices, especially central venous catheters.[154] Bacteremias remain the site with the highest case-fatality rate, exceeding 25% in many reports.[155–157] In addition, they cause a significant economic burden with a marginal cost estimate of $25,000 per episode.[151,158,159] Nosocomial bloodstream infections are reported as secondary to another site if there is documented infection at the primary site (in which case they are not included as an additional infection in determining rates) or primary if there is a culture-confirmed bacteremia without evidence for an underlying site of infection. Secondary bacteremias are documented in over 5% of infections at all sites and are most commonly associated with cardiovascular, intra-abdominal, and intravascular sites of primary infection. Infections with gram-negative organisms, including *Acinetobacter, Bacteroides*, and *Serratia*, have the highest rates of secondary bacteremias but are exceeded by far in relative frequency by *S. aureus* and coagulase-negative *Staphyloccus* infections.

Primary bacteremia rates are highest in teaching hospitals in the CDC–NNIS system, making up over 16% of infections in the larger teaching hospitals. The gram-positive organisms of coagulase-negative staphylococci and *S. aureus* have increased to become the most common agents of primary bacteremia in all but gynecology services where *E. coli* and *Bacteroides* species remain the most frequent. Recent data suggest that even among the general hospital population, bloodstream infections due to gram-negative organisms are again beginning to increase in number.[160]

5.1.4.5. Cutaneous Infection. Cutaneous infections make up approximately 6% of the infections reported from the NNIS system, with high rates in the larger university hospitals and on the newborn units. A larger portion of infections

in the developing countries and in extended-care facilities in the United States are reported at a cutaneous site.[122,124] *S. aureus* is the most frequently reported isolate at this site, with aerobic and anaerobic gram-negative rod organisms of increasing importance at this site in pressure ulcers common to the elderly in extended care.

5.1.4.6. Other Types of Nosocomial Infections. While the previously mentioned infections account for the clear majority of nosocomial infections, many other types of infection (e.g., gynecological, other upper respiratory, eye, gastrointestinal) may also occur in the healthcare setting.[79]

5.2. Epidemic Behavior and Contagiousness

Epidemic nosocomial infections represents only 5% of all nosocomial infections, yet they have been the most extensively reported. Epidemic behavior is determined by the causal bacteria, the route of transmission, and the characteristics of the host population at risk. These epidemics have mirrored advances in medicine just as the most common causal agents have moved from gram-positive streptococcal wound and puerperal infections, through resistant staphylococcal epidemics, to gram-negative bacilli of increasing antibiotic resistance infecting hosts with decreasing ability to resist.[161,162] In contrast, endemic nosocomial infections with gram-positive organisms have been increasing over the last decade compared to endemic gram-negative infections. Nosocomial epidemics investigated by the CDC have doubled each 5-year period since 1960.[163] During the period 1970–1975, 42% of the epidemics investigated were associated with some medical device and 70% were due to gram-negative bacilli.[164] From 1980 to 1985, 46.6% of the outbreaks investigated were related to products, procedures, or devices, and this proportion rose to 67.3% of investigations for the period 1986–1990.[162] Gram-negative bacteria accounted for 66% of the investigated outbreaks. Outbreaks of infection due to vancomycin-resistant enterococci have been increasingly reported in intensive-care units and oncology units, especially from large teaching hospitals.[165,166] More recently, outbreaks due to extended-spectrum beta-lactamase (ESBL)-producing Enterobactericeae as well as multidrug-resistant *P. aeruginosa* and acinetobacter species have been increasingly reported.[167–171] While this experience may represent unusually interesting or difficult outbreaks, it is not unusual for larger medical centers to experience several epidemics per year.

Many pseudoepidemics have been reported.[172–174] A pseudoepidemic is the occurrence of an increased number of isolates of a microorganism misinterpreted as a true epidemic of infection. The main factors in the psuedoepidemics have been improper specimen processing, surveillance artifact, and clinical misdiagnosis.[93]

5.3. Geographic Distribution

Nosocomial infections are not limited by geography (Table 2).[4] Lack of reported nosocomial infection has indicated inadequate study more frequently than an absence of risk. Service, organism, and extent of morbidity and mortality vary within and among different institutions. This variation frequently reflects differing case mix (severity of disease, comorbid factors) in the samples admitted from the population served. As a result, it is common for tertiary-care centers to exhibit higher rates than primary-care hospitals.[3,9] A direct relationship between rates of specific community-acquired infections and nosocomial risk has not been documented. However, the appearance of nosocomial epidemics as extensions of community-acquired and propagated epidemics has been recognized, as has the converse.[175] An excellent recent example of the impact of community infections propogated within the healthcare setting is the rapid emergence of community-associated MRSA.[176–178]

5.4. Temporal Distribution

An unexplained seasonal variation in certain gram-negative rods, including *Acinetobacter* with summer peaks, has been reported.[179,180] A recent study evaluated the association between weather patterns and occurrence of legionellosis, finding that cases of legionellosis occurred with striking summertime seasonality.[181] A significant dose–response relationship for occurrence of cases was seen with both precipitation and increased humidity. This finding is consistent with the current understanding of the ecological profile of legionella and supports the contention that sporadic disease due to this pathogen occurs through contamination of water sources.[181]

A direct correlation has been suggested between length of stay in a hospital and the incidence of nosocomial infection, but the confounding variables of disease severity, age, and comorbidity complicate this association. However, it is clear that the longer a person is hospitalized, the greater the likelihood exposure to possible risk factors for infection (e.g., indwelling devices, antimicrobial use, healthcare worker interactions).[182]

5.5. Age

Although persons ≥65 years of age comprised only 4% of the US population in the early 1900s, this group now

account for 13% of the total US population.[183] The number of US citizens living into extreme old age is growing exponentially with the most rapidly growing segment composed of individuals aged ≥85.[184] Currently, over 1.7 million people reside in over 17,000 long-term care facilities (LTCFs) in the United States, with this number expected to increase to 5 million by 2030.[185,186] Between 1.6 and 3.8 million infections occur in LTCF residents in the United States each year.[185,187–189] Extremes of age have been reported as directly associated with increasing nosocomial infection rates,[190] and the special problems in children[191] and in surgical site infection[192] have been recorded. Since extremes of age are known to be correlated with host defects resulting in increased susceptibility to infection, this hypothesis seems reasonable and attractive. Unfortunately, most studies have reported only relative frequency of infection by age group and have not been well controlled for length of exposure, disease severity, treatment, or other patient-related conditions that predispose to infection. Daschner et al.,[18] in a retrospective autopsy study, found an excess of nosocomial deaths in the 20–60-year-old age range. In a controlled study of risk factors for nosocomial infection in a university medical setting, age of 65 years or older increased the risk of nosocomial infection three times.[25]

Morbidity and mortality from nosocomial infection increase directly with age in the elderly, as for most infections, and the special problems of the neonate are similar to other infections in that age group.

5.6. Sex

Incidence of nosocomial infection has been reported to be greater in males than in females, but as with most other variables, these studies have not been well controlled.[157] Sex-related morbidity and mortality for nosocomial infection seem to parallel the site-pathogen experience for individual diseases.

5.7. Race

No race difference has been suggested or reported for nosocomial infections independent of other disease processes.

5.8. Occupation

Clinical healthcare professionals, medical laboratory workers, and other support personnel who come into contact with patients or patient specimens have potential increased risk of bacterial infection related to their employment.[193] Individual cases and outbreaks of a variety of bacterial infectious diseases (often *S. aureus* or MRSA) have been reported.[194–197] The most well-documented increased risk for clinical workers appears to be tuberculosis.[198,199] Medical laboratory personnel share this increased risk of tuberculosis and may have increased rates of brucellosis, shigellosis, *S. aureus*, and other enteric bacterial diseases.[197,200]

5.9. Occurrence in Different Settings

Healthcare-acquired infections have been reported in both acute- and extended-care settings. Within acute-care hospitals several high-risk units for nosocomial infection have been recognized. These include burn units,[198] high-risk nurseries,[191] intensive-care units,[161,201] dialysis units,[202,203] transplantation units,[204,205] and oncology units.[120] The common denominator in these units appears to be the use of specific hospital procedures and the presence of more severely compromised patients. The high nosocomial infection rates reported for university teaching hospitals may be directly related to the presence of these high-risk units. In one study of 38 US hospitals, 25% of all nosocomial infections reported occurred in intensive-care unit patients.[161]

Between 1.6 and 3.8 million infections occur in LTCF residents in the United States each year.[185, 187–189] Infections account for up to 50% of hospital transfers and 300,000 hospital admissions among LTCF residents annually.[206–208] Among LTCF residents, estimates of mortality from infection range as high as 388,000 deaths per year.[184,185,187,188] The annual cost of antibiotic therapy to treat infections in LTCF residents ranges from 38 to 137 million,[209,210] while costs of hospitalizations of LTCF residents due to infection range from 673 million to 2 billion each year.[209,210]

The proportion of medical care that is provided in the outpatient setting is increasing rapidly. For example, 80–90% of all cancer care is delivered in the outpatient setting and more than half of all hospital-based operations are done in ambulatory surgery centers.[211] From 1992 to 2001, patient visits to hospital outpatient departments increased from 56.6 million to 83.7 million visits. This represents a 48% increase, although the population in the United States increased by only 12% during the same time period. Office-based physician practices account for 80% of ambulatory healthcare delivered by non-Federal physicians, with 880.5 million patient visits in 2001.[212] While there is a recognized need for increased understanding of the epidemiology of nosocomial infections in this setting,[213] few data exist to date.

5.10. Socioeconomic Factors

While the importance of socioeconomic factors in infectious disease epidemiology is well recognized, no differential

has been reported for nosocomial infections independent of other disease processes.

5.11. Other Host Factors

In addition to age, the genetic and acquired modifications of host defenses usually important in increased susceptibility to infection contribute to nosocomial risk (Table 4). They include metabolic disease, cardiovascular disease, respiratory disease, cutaneous disease, and a spectrum of hematologic and immunologic abnormalities. Among the host defenses altered by these diseases are modifications in normal flora, changes in anatomical barriers to microorganisms, suppression of inflammatory response, and modifications in the reticuloendothelial system. Among the hematologic and immunologic factors important in nosocomial infection are those that decrease the number of neutrophils, cause defective function of neutrophils, reduce or cause defective immunoglobulin production, or interfere with cellular immunity. A single underlying condition may contribute to several defects in host defenses. A solid tumor may cause obstruction, erode a mucosal surface, and metastatically replace bone marrow. The resultant malnutrition, easy portal of entry, and loss of leukocyte function all contribute to infection by opportunistic microorganisms. The conditions that predispose to such opportunistic infections and the types of organisms involved have been well reviewed elsewhere.[214–216]

5.12. Treatment Factors

5.12.1. Antibiotics. Between 25 and 35% of hospitalized patients receive systemic antibiotics. Antibiotic treatment, including prophylactic antibiotic use, contributes to the risk of nosocomial infection by several means.[217] In addition to modifying the endogenous microflora of the host, several antibiotics interfere with immune function (chloramphenicol, rifampin) or contribute to renal (aminoglycosides), hepatic (erythromycin, isoniazid), or cutaneous (β-lactams) side effects that increase susceptibility to infection.

Under pressure of antibiotic use or abuse, the environmental microbial flora of medical care institutions increases in antibiotic resistance.[21, 113, 218–220] Patient acquisition of these resistant microbial flora begins shortly after admission and is accelerated by antibiotic treatment or prophylaxis, reaching as much as 60% of the patient population by the third week in some studies.[107] This acquisition is paralleled by an increase in the appearance of these bacteria in the causation of nosocomial infection (see Chapter 4).

5.12.2. Other Drugs. Those drugs with side effects that decrease normal host defenses have the most profound role in increasing risk of nosocomial infection. Corticosteroids modify inflammatory response, interfere with leukocyte function, and depress cellular and humoral immune responses. Antimetabolites and a variety of other cancer chemotherapy drugs have profound effects on all rapidly proliferating tissue, resulting in hemopoietic side effects that decrease immune function and gastrointestinal

Table 4. Examples of Factors that Modify Host Defenses

Host defenses	Disease modifiers	Treatment modifiers	Frequent sites of infection	Common organism of infection
Normal flora	Thermal burn	Antibiotic therapy	Soft tissue	*Pseudomonas*
		Gastric surgery	Intestine	*Salmonella*
Anatomical barriers	Trauma	Medical devices	Intravenous site	Coagulase-negative staphylococci
		Surgery	Wound	*S. aureus*
Mucociliary clearance	Cystic fibrosis	Irradiation	Pulmonary	*S. aureus*
		Tracheostomy	Pulmonary	*Pseudomonas*
Reticuloendothelial system	Sickle-cell disease, asplenia	Hemodialysis	Bloodstream	*S. pneumoniae* *H. influenzae* *Salmonella*
Leukocyte function	Chronic granulomatous disease, Job's syndrome, diabetic ketoacidosis	Corticosteroids Drug-induced neutropenia	Soft tissue Pneumonia	*S. aureus*
Humoral immunity	Agammaglobulinemia, chronic lymphocytic leukemia, multiple myeloma	Immunosuppression Cancer chemotherapy	Soft tissue Pulmonary	*H. influenzae* *S. pneumoniae* Gram-negative aerobes
Cell-mediated immunity	Thymic aplasia, malnutrition, Hodgkin's disease, HIV/AIDS	Immunosuppression Corticosteroids	Soft tissue	Gram-negative aerobes *Mycobacterium tuberculosis*

Table 5. Common Device-Related Nosocomial Infections[a]

Device[b]	Hospitalized patients with the device (%)	Most common related infection	Patients developing infection (%)	Case-fatality rate (%)
Urinary catheter	10	Bacteruria	20	<1
Intravascular infusion	12	Suppurative phlebitis	<0.01	20–40
Scalp vein needle	12	Suppurative phlebitis	<0.01	20–40
Plastic catheter	12	Suppurative phlebitis	0–8	20–40
TPN	0.1	Suppurative phlebitis	0–27	20–40
Arterial catheter	0.2	Suppurative phlebitis	0.2	20–40
Respiratory therapy				
Continuous ventilator	2	Pneumonia	—	40
IPPB	7	Pneumonia	—	40
Hemodialysis		Shunt infection	15–20	5

[b]TPN, total parenteral nutrition; IPPB, intermittent positive-pressure breathing.

side effects that interfere with secretory protection and cause loss of anatomical barriers through ulceration. The patient treated with a combination of intensive chemotherapy, immunosuppressive agents, and antibiotic prophylaxis in an attempt to induce remission of leukemia or in preparation for bone marrow or organ transplantation epitomizes the host at special high risk of nosocomial infection secondary to drug effects.

5.12.3. Device- and Procedure-Related Infections. Medical implements and devices and the procedures associated with them have assumed a common necessary part of modern medical practice. These devices include intravenous catheters, drains, urinary catheters, indwelling tubes placed into the normally closed body cavities of the peritoneum or the cardiothoracic spaces, prosthesis in the cardiovascular system, the central nervous system, or the skeletal system, as well as a variety of implements in the respiratory system, including nasotracheal, endotracheal, and tracheostomy tubes. Each of these devices provides a route of entry for microorganisms by penetrating host defense mechanisms and acts as inanimate foci for the proliferation of microorganisms. One or another of the devices is used in the care of approximately 10% of patients hospitalized in acute-care facilities. It has been estimated that 45% of all nosocomial infections, over 850,000 per year in the United States, are device related (Table 5).(9,164,221)

6. Mechanisms and Routes of Transmission

Patients may be infected with bacteria acquired from either endogenous or exogenous sources. Microorganisms from endogenous sources may appear by reactivation of some previous infection, as in tuberculosis, or by invasion of commensal flora, which infect because of some reduction in host defenses. Transmission from exogenous sources may take place by hands, by the airborne route, through fomites, by insects, or by ingestion of contaminated food or water. While each of these routes, with the exception of insects, has been described in individual outbreaks, transmission by direct and indirect contact remains the common and most significant route in acquiring nosocomial infection. Exogenous sources are found in three specific reservoirs: (1) within the fixed structures of the facility itself; (2) in devices or equipment used within the institution; and (3) in medical personnel, other patients, or visitors.

6.1. Inanimate Reservoirs

The microenvironment of the hospital, rich in water and nutrient sources, has provided a continuing niche for gram-negative bacilli that have evolved as important agents in nosocomial infection. *Enterobacter, Serratia, Acinetobacter, Citrobacter, Flavobacteria, Legionella*, and *Pseudomonas* species have been repeatedly identified as important nosocomial pathogens because of their ability to survive in the aqueous and other fluid reservoirs of our institutions.(167,222–225) Clean environmental surfaces are generally not important sources of bacteria-causing nosocomial infections.(68) However, environmental surfaces contaminated with *Clostridium difficile* or vancomycin-resistant enterococci have been implicated in the nosocomial transmission of these organisims.(226,227) Extensive reviews of reported inanimate reservoirs are available.(225,228)

6.1.1. Structural or Engineering Reservoirs. The medical care field is one of rapid change, and this is evident in frequent requirements for modification of structures used for medical care. With limited funding, compromises in terms of structure, space, and function that are less than ideal may be accepted. The result may be crowding,

which encourages cross-contamination, or the inconvenient placement of certain fixed equipment (e.g., hand-washing sinks), which makes the use of the equipment problematical. Construction or reconstruction has also been associated with increased rates of nosocomial fungal infection. Furthermore, reconstruction may disguise an inadequate air-conditioning system, resulting in the recirculation of unfiltered air from an "isolated" tuberculosis patient[193] or of air exhausted from microbiological laboratories or other areas of high biohazard.

Legionella pneumophila is ubiquitous in water and may be present in potable water. Nosocomial Legionnaires' disease has been described as resulting from contaminated cooling towers of air-conditioning systems and potable water as well as from construction activity in the vicinity of the hospital.[229–232] Reservoirs of nosocomial bacteria within water supplies or plumbing have been a recurrent problem in hospitals caring for high-risk patients.[222,223,233]

6.1.2. Equipment Reservoirs. In addition to the common medical devices, a wealth of new and increasingly complex equipment attends patient care. Respiratory assistance equipment, cardiovascular assistance pumps, microelectronic monitoring devices, dialysis machinery, and numerous other "black boxes" have reached the bedside. Appropriate use of these instruments is understood by fewer and fewer individuals, and the safe techniques for appropriate disinfection between patients may be overlooked or misunderstood. Portions of this equipment may be expensive, fragile, nondisposable, and unable to withstand the usual harsh but sure techniques of heat sterilization. Alternate methods are often less well understood than classic heat sterilization, and inadequate attention is paid to the detail necessary to assure their full implementation. As a result, residual microorganisms may be transmitted to subsequent patients as has occurred with a variety of devices, including bronchoscopy and endoscopy equipments.[219,234–236] Other problems have arisen when bacterial endotoxins have remained on equipment, causing severe reactions, or residual chemical sterilants themselves have caused toxic effects.[237]

6.2. Animate Reservoirs

Bacteria causing nosocomial infection may reside in the animate reservoirs[109,164,238–242] of the healthcare worker or of the chronically institutionalized patient. Patients colonized with nosocomial organisms at clinical sites, such as wounds or urine, or colonized in their gastrointestinal or genitourinary tract, or their oropharyngeal flora serve as reservoirs for these organisms.[112,243,244] Hospital personnel are occasionally personal carriers of nosocomial organisms such as *Salmonella*, staphylococci, or enterococci that are transmitted to hospitalized patients. Of these characteristics, the ability to survive at the time of transmission in mechanical carriage remains the most significant factor in nosocomial infection.

Hospital professionals, medical support workers, and patients provide the animate reservoirs for microorganisms. Biological transmission through symptomatic or asymptomatic carriage of bacteria has led to serious and extensive epidemics.[163,239] While visitors are a potential for microorganisms, they have rarely been implicated in such transmission.

Even more commonly, healthy but careless individuals mechanically transmit large numbers of bacteria from reservoirs within the facility, from equipment, and from patient to patient during their daily rounds.[245] Hand carriage of microorganisms is recognized as the most important factor in endemic and most epidemic spread of nosocomial infection. Multiple investigations conducted during the last 40 years have confirmed the important role that contaminated hands of healthcare workers play in transmission of healthcare-associated pathogens.[246] As a result, hand washing has for many years been considered one of the most important measures for preventing the spread of pathogens in healthcare settings.[247] In one study in a university neurosurgical unit, 44% of randomly sampled personnel carried gram-negative bacilli and 11% had *S. aureus* on their hands.[248] More important, serial culturing demonstrated that all persons at various times carried gram-negative bacilli and two-thirds carried staphylococci. Indirect contact spread via transient hand carriage has been implicated in other nosocomial transmission of staphylococci, enterococci, and gram-negatives.[109,238,240,242,249] Such carriage is instrumental in the nosocomial colonization that precedes infection in the compromised host.[106,107,241,250,251]

7. Pathogenesis and Immunity

The pathogenesis of nosocomial infection is determined by host and environmental factors that are uniquely combined in healthcare institutions.

The susceptible patient is prey to all the conventional pathogens. The compromised host is infected by a much smaller dose of bacteria and by species that are usually considered commensal and "nonpathogenic."[214] Thus, the host with underlying severe disease and impaired host defenses has higher rates of infection, secondary bacteremia, refractory infection, and case fatality.[17,252] As in the example of hematologic cancers, disease and treatment have so devastated the immune system that response is lethargic or nonexistent, infection is poorly controlled, even by

appropriate antibiotic therapy, and case mortality is high.[253] Following infection with agents that persist in endogenous sites (e.g., *M. tuberculosis*), significant immune depression may result in reactivation and uncontrolled dissemination.

Pathogenicity by nosocomial agents has not been related to the presence of resistant bacteria.[254,255] However, antimicrobial resistance has been frequently associated with worse clinical outcomes.[10] One possible explanation is noted in recent studies focusing on bloodstream and respiratory tract infections in hospitalized patients which suggest that a delay in adequate antimicrobial therapy results in significantly poorer outcomes, even when controlling for other important predictors of mortality.[55,56,256–259] One common reason for prolonged time to adequate therapy is that choices for empiric therapy did not ultimately match the organism identified (often due to infection with a resistant pathogen).[53,55]

The selective pressure of antibiotic use assures the presence of resistant forms available for transmission in the healthcare setting.[243] At each site, colonization precedes local multiplication and tissue infection.[106,260,110] Colonization with nosocomial organisms results from alterations in "normal flora" by broad-spectrum therapy, hospitalization, and instrumentation. Colonization is directly related to the organisms' survival ability, ability to adhere to mucosal surfaces and catheters, and organism virulence. Special procedures and devices allow bacteria to be delivered past the superficial barriers and to sustain a milieu important to implantation and multiplication.

8. Patterns of Host Response: Clinical Features and Diagnosis

Patterns of host response to nosocomial infection are those classically described with bacterial disease of the sites involved. As with pathogenesis, clinical features and morbidity are determined by the virulence of the agent, the dose and route of transmission, and the character of the host defense mechanisms.

Signs and symptoms in the compromised host may be altered or reduced. Fever may be low or absent. The site of infection may be unusual, as in the predilection to perirectal abscess in cancer patients.[261]

8.1. Urinary Tract Infection

Infections of the urinary tract account for one third of all nosocomial infections.[4,24,105,132] Urinary tract infections are also the most common cause of infections in the long-term care facilities. *E. coli, E. faecalis*, and *P. aeruginosa* are the most common causal organisms.[21] The great majority of healthcare-associated UTIs result from instrumentation of the urinary tract, usually catheterization. Catheterization is a common practice; approximately 15–25% of hospital patients have a urinary catheter at some time during their stay, with rates of utilization varying by unit type within the hospital.[262] Indwelling urinary catheters are also very common in LTCF residents.[133] The risk of contracting catheter-associated UTI increases with the duration of catheterization.[263] Females, the elderly, and persons with severe underlying illness are also at increased risk of healthcare-acquired urinary tract infection.[236] The overall risk of bacteriuria in hospitalized patients with indwelling catheters is about 25%. Bacteria gain access to the catheterized bladder by either of two routes. They may migrate from the collection bag or the catheter drainage tube junction, or ascend extraluminally within the periurethral space.[260] Bacteria can adhere to and grow on the inner surface of the catheter, leading to a biofilm that also includes urinary proteins and salts. Bacteria embedded in this biofilm are then less susceptible to antibiotics.[264,265] Although urinary tract infection is typically characterized by dysuria, frequent and/or urgent urination, bacteriuria, and pyuria,[266] these findings may be attenuated or absent in the elderly or in immunocompromised patients. Greater than 10^5 colony-forming units per milliliter of urine represent significant bacteriuria from a clean-catch midstream urine specimen. In catheterized patients, however, a concentration of microorganisms considerably less than 10^5 can be shown to increase if untreated and can be associated with symptomatic infection.[267] The significance of asymptomatic bacteriuria in patients with indwelling bladder catheters remains under discussion.[135,268] Recent guidelines concerning asymptomatic bacteriuria from the Infectious Diseases Society of America suggest that urine cultures not be obtained in asymptomatic catheterized patients.[269] Furthermore, the goal of therapy of asymptomatic catheter-associated bacteriuria remains poorly defined with bacteriuria recurring shortly after cessation of antimicrobial therapy.[269]

8.2. Nosocomial Pneumonia

Pneumonia appears frequently in patients in whom aspiration has taken place or in whom the upper airway is bypassed by endotracheal intubation. The diagnosis of nosocomial pneumonia is difficult to make and often relies on the combination of clinical criteria and microbiological data.

Purulent sputum, pulmonary infiltration on X ray, fever, and hypoxia may indicate the presence of this complication. In individuals with community-acquired pneumonia, a change in microbial flora in the sputum accompanied by a worsening in clinical course usually indicates a pulmonary superinfection. Culture and Gram's or other staining of the sputum are important in establishing the etiologic diagnosis.[86,143,270] Protected specimen brush samples or bronchoalveolar lavage is important in more clearly defining the microbial etiology of nosocomial pneumonia.[145] Organisms simultaneously isolated from the blood and pleural fluid are strong evidence of pulmonary infection with that agent.

8.3. Surgical Site Infection

Infection of the surgical site is suspected in any febrile postoperative patient. Drainage of purulent material or disruption of the wound is considered prima facie evidence of wound infection regardless of the presence or absence of bacterial isolates. Unfortunately, up to 60% of surgical site infections are not evident until after the patient is discharged from the hospital which makes tracking of these infections difficult.[140] Infection following certain procedures such as implantation of a prosthesis or other foreign material may only become evident after months.

8.4. Bacteremia

Bacteremia is usually accompanied by fever and a decline in clinical condition. In the absence of evidence of infection at other sites, an intravenous source of infection should be suspected. Intravascular catheters in place for more than 48 hours should be investigated, even in the absence of inflammation.[271] Blood cultures, cultures of infusates, and semiquantitative cultures of the catheter itself may establish the diagnosis.[272] A recent meta-analysis noted that paired quantitative blood culture is the most accurate test for diagnosis of central venous catheter-related bloodstream infection.[273] However, most other methods studied showed acceptable sensitivity and specificity and negative predictive value. The positive predictive value of all tests increased with high pretest clinical probability.[273]

8.5. Infection at Other Sites

Nosocomial infection of the skin, soft tissue, gastrointestinal tract, urogenital tract, and other sites may be found. More detailed discussion of the appearance, diagnosis, and treatment of these infections has been published.[274,275]

9. Control and Prevention

9.1. General Concepts

The methods for conducting a successful nosocomial infection control program have been recently reviewed[78] (Table 6). Identification of nosocomial infections through application of standard criteria is widely accepted.[9] Routine, continuous collection, collation, evaluation, and reporting of these data by a trained specialist using "surveillance" tools are recommended and have been tested for efficacy by the CDC during the SENIC Project[28] (see Chapter 2). The presence of the infection control professional (ICP) on the clinical unit is also of value in (1) reinforcing the importance of infection control measures; (2) providing early identification of epidemics; (3) providing informal, concurrent, in-service education; and (4) assisting in providing new information for research efforts in the area of nosocomial risk control. The presence of one ICP for approximately every 250 inpatient beds is important to efficacy. However, it has been noted that this ratio is no longer adequate as the amount and complexity of the work of the ICP has increased, the care of patients in the healthcare setting has become more complex, and the severity of illness of the hospitalized patient population has continued to increase.[78] The presence of a trained hospital epidemiologist is also of great value.[78] Evaluation of institutional nosocomial infection data through these techniques has allowed identification of priority infection problems and planning, implementation, and evaluation of interventions to control them. Control programs usually fall into three areas: preventive engineering, equipment control, and personnel programs.

9.1.1. Preventive Engineering. Infection control personnel must collaborate with engineers, nurse managers, administrators, architects, and physicians before, during, and after construction or reconstruction projects. Various

Table 6. Elements of Nosocomial Infection Control

guidelines have been published by professional societies as well as state and national agencies.[276–278] Efficient function follows appropriate form in the hospital as in other industries. If hand-washing sinks are present and conveniently placed in patient care areas, it is more likely that they will be used. Traffic flow will be determined by design and will be difficult to alter by placing signs thereafter. Control of environmental bacterial contamination will be affected by surface features, air-conditioning, and the convenient presence of housekeeping and other service modules.

9.1.2. Equipment Control. As with structure, the design of equipment is important to its correct use, maintenance, and disinfection. Initially inexpensive devices may multiply future costs by requiring complicated disassembly, cleaning, and time-consuming disinfection in order to render them safe for multiple patient use. Component parts may not tolerate heat sterilization and may require gas or chemical sterilization. Gas and chemical sterilizations are more demanding in detail and may leave residuals that present toxic problems.[237] The use of disposable equipment has exploded in the hospital industry, contributing to major increases in cost and in problems of waste disposal. Reuse of disposable equipment on individual patients, under strict protocols, has been found acceptable in a few limited situations (e.g., hemodialyzer reuse).[270,279,280] However, attempts to modify this expense by reuse of disposable equipment on multiple patients have been responsible for several outbreaks of nosocomial infection and are to be decried.[281] Intrinsic contamination of industrially prepared medical devices and supplies has been a rare cause of epidemic nosocomial outbreaks and has usually been associated with and identified by the unique bacteria involved.[248,282]

9.1.3. Personnel Programs. Healthcare personnel are the common final factor in the transmission of most nosocomial infections. Orientation and in-service education and reeducation programs are important in gaining staff appreciation of infection control programs and techniques. The direct availability of the ICP during on-the-ward surveillance activities provides important one-on-one education and consultation in support of bedside infection control. Behavior modification through management techniques of observation, retraining, and the use of incentives and penalties is recommended and under expanding use as effective infection control efforts.[283] Occupational health programs, which assure that healthcare workers are screened and vaccinated as indicated, for transmissible diseases on employment and have the opportunity to have subsequent illnesses evaluated for potential transmission, are also an important feature of control of animate reservoirs. [284–286]

9.2. Special Control Programs

9.2.1. Hand Washing. Routine hand washing before, between, and after contact with patients is recognized as the most important feature of successful infection control.[78,246,247] The use of an antiseptic soap is recommended in high-risk areas and when vancomycin-resistant enterococcus is isolated,[227] but otherwise is of little documented improvement over the routine use of a vigorous scrub with soap and running water. The use of gloves does not replace the need for hand washing. In a recent study involving 2,800 observed opportunities for hand hygiene in a large hospital, factors associated with poor compliance with hand hygiene included a high intensity of care (i.e., many opportunities for hand hygiene per hour of patient care), weekdays, working in an intensive-care unit (ICU), and procedures associated with a high risk of contamination.[287] Poor adherence associated with a high intensity of care suggested that HCWs did not have enough time to wash their hands as frequently as recommended.[287] Alcohol-based hand rubs (gels, rinses, foam) have characteristics that address several problems associated with washing hands with soap and water. Alcohol solutions reduce bacterial counts of the hands of volunteers to a greater degree that washing hands with nonantimicrobial soap and water, and antimicrobial soap and water.[246] Also, because alcohol-based hand rubs do not require the use of water, they can be made available at many more locations than hand-washing facilities. Finally, making such products readily accessible (near each patient's bedside or in pocket-sized bottles) has been shown to improve adherence of HCWs to recommended hand hygiene practices.[288] In ICUs, where the workload is high, with corresponding elevated numbers of indications for hand hygiene per hour of patient care,[287] preferential use of handrubs can reduce the impact of time constraints, with subsequent improvement in compliance.[289] Extensive reviews of hand-washing procedures and guidelines have been published.[33,67,245,246,290]

9.2.2. Standard Precautions and Isolation Control. The goal of isolation is to prevent transmission of microorganisms from infected or colonized patients to other patients, hospital visitors, and healthcare workers. Personal protective equipment (e.g., masks, eyewear, gloves, and gowns) and specific room requirements are critical in accomplishing this goal. Appropriate isolation remains the cornerstone of infection control and is assuming greater importance as the prevalence of multiply antibiotic-resistant organisms increases.

Techniques for the recognition and appropriate care of patients with potentially communicable disease have been recommended in guidelines published by the CDC.[291] The recognized inability to identify accurately all such individuals on admission and the potential for healthcare worker

exposure to HIV and other blood-borne disease(s) have led to the recommendation that a modified method of care be used for all patients with whom there is expected to be contact with blood or body fluids. This system of "universal precautions" recommends the use of gloves in any patient care situation where such contact is expected and the additional use of gown, mask, and eye protection where splashing, aerosolization, or more extensive exposure is common.[291]

In the CDC guideline, there are two tiers of precautions.[291] The first tier is referred to as *standard* precautions and is to be used for the care of all patients, regardless of diagnosis. Standard precautions incorporate the major features of both universal precautions and body substance isolation and are designed to reduce the risk of transmission of organisms, including blood-borne pathogens, to patients and healthcare workers. The second tier, referred to as *transmission-based* precautions, includes airborne precautions, droplet precautions, and contact precautions. These precautions are designed for the care of specific patients infected or colonized with epidemiologically significant organisms that are spread by the airborne or droplet route or by contact with dry skin or contaminated environmental surfaces. These precautions are to be used in addition the standard precautions.

9.2.3. Epidemic Investigation and Control. The routine collection of surveillance data on nosocomial infections allows one to establish endemic rates by type of nosocomial infection, by organism, and by area and service within the medical facility. This allows rapid recognition of unusual or epidemic events, whether through the appearance of a new or highly resistant microorganism or through a grouping of similar infections. Advances in information technology has allowed a more systematic and streamlined approach to establishing baseline rates of infection and setting triggers for evaluation of a possible outbreak.[35,36] An outline of an epidemic investigation is given in Table 7. The careful documentation and reporting of epidemic investigations are important features in every infection control program.[292]

9.2.4. Nosocomial Urinary Tract Infection. The vast majority of documented nosocomial urinary tract infections are associated with catheter use. The use of a closed sterile drainage system with indwelling catheters provides a significant (50%) short-term reduction in infection related to this device.[293] Appropriate care in the placement and maintenance of these devices is essential to their success in preventing nosocomial infection.[260,294] Breaks in aseptic technique in placement and disruption and entry into the closed system are the most significant factors in the development of catheter-related urinary tract infection.[295] Despite the clear risk, catheters are often overutilized and unnecessary, placing patients at needless risk of contracting infection.[263] Better methods of monitoring catheter utilization and reducing the inappropriate use of urinary catheters translate into reduced rates of healthcare-associated UTIs.[296] Guidelines for the control of nosocomial urinary tract infection have been developed and published by the CDC.[297] An outline for catheter use and care is seen in Table 8.[298] In the SENIC project analysis, the combination of high levels of surveillance activity, a modest level of control activity, and the presence of a full-time ICP yielded an estimated 31% reduction of infection in patients at high risk for this event.[299] Asymptomatic bacteriuria is a common finding and the latest IDSA guidelines recommend that cultures be performed in pregnant women and individuals about to undergo a urologic procedure.[269] Screening cultures in asymptomatic individuals should not be performed.[269] Recent attention has also been paid to the role of urinary catheters coated with antimicrobial substances. A recent systematic review summarized the results of studies performed to date evaluating nitrofurazone coated or silver alloy coated urinary catheters.[294] Both types of antimicrobial-coated catheters can prevent bacteriuria during short-term catheterization in hospitalized patients. Evalution of the impact of coated catheters on symptomatic UTI was not assessed in any of the reviewed studies.[294]

9.2.5. Nosocomial Surgical Site Infection. Nosocomial surgical site infections are usually initiated at the time

of surgery.[300–302] The responsible microorganisms originate from the patient's endogenous flora, from operating room personnel, or from the operating room environment. Guidelines featuring the etiology and control of surgical site infections have been published by the CDC.[141,279] Reporting SSI rates to practicing surgeons has been shown to reduce rates, likely due to having one's behavior observed. However, one must interpret the conclusions with caution as most studies have included confounding factors.

One must ensure that best practices are followed for proper hair removal and antiseptic skin preparation. Patients who are colonized with *S. aureus* in the anterior nares are at increased risk of the development of surgical site infection as well as other nosocomial infections.[303] A recent randomized double-blind clinical trial demonstrated that treatment with preoperative mupirocin decolonized the nares of patients and decreased *S. aureus* nosocomial infections in only a subset of patients who were colonized.[303] Treated patients also had decreased *S. aureus* SSI, but the decrease was not statistically significant. Further study is needed to determine if this intervention can benefit a targeted subset of surgical patients. Of note, a recent study noted that routine culture for *S. aureus* nasal carriage at admission and subsequent mupirocin application did not provide effective prophylaxis against nosocomial *S. aureus* infections in nonsurgical patients.[304]

The routine use of prophylactic antibiotics just prior to selected surgical procedures has been well studied, and the practice is supported by an ever growing number of investigations. Prophylactic antibiotics are meant to decrease microbial proliferation at the incision site. The timing of prophylactic antibiotics is crucial in determining efficacy in preventing surgical site infections. The optimum time for administration has been shown to be during the 1 hour period before the incision.[305] Antibiotic prophylaxis is recommended for clean-contaminated procedures and clean procedures involving the implantation of a foreign body. Several reviews of these recommendations have been published.[306–308] General guidelines for the approach to surgical prophylaxis are reviewed in Table 9. Recent studies have shown that there is much room for improvement in the administration of antimicrobial prophylaxis.[305] Indeed, the Centers for Medicare and Medicaid Services (CMS) has made proper administration of preoperative antibiotics, a quality performance standard for hosptials.

Proper ventilation should be maintained in all operating rooms, including positive-pressure and appropriate air filters. In addition, traffic through the operating room should be kept to a minimum. Normothermia should be maintained during surgery as studies have demonstrated that intraoperative hypothermia approximately triples the risk of surgical site infection and leads to many other adverse events.[309] Likewise, hyperglycemia increases the likelihood of surgical site infection.[310] Thus, interventions to screen for diabetes and hyperglycemia with administration of intensive insulin therapy should be considered.

9.2.6. Nosocomial Respiratory Infections. Preventive strategies to lower the incidence of nosocomial pneumonia focus on reducing or eliminating risk factors for oropharyngeal or gastric colonization and subsequent aspiration of contaminated oropharyngeal or gastric secretions. Recent guidelines for prevention of healthcare-associated pneumonia have been published.[311] Data from the SENIC project suggest that a high level of surveillance and the presence of an ICP were a necessary feature for the 27% reduction in postoperative pneumonia reported. Reductions in medical pneumonia appeared much less successful.

Endotracheal intubation is one of the most important risk factors contributing to pneumonia in patients requiring mechanical support for respiratory failure. Increasingly, the use of non-invasive or positive-pressure mask ventilation in selected groups of patients has been shown to be effective in reducing the need for endotracheal intubation.[312] While not appropriate for all patients, the use of non-invasive ventilation in selected populations appears safe and may reduce the likelihood of nosocomial pneumonia.[313]

Supine patient positioning may contribute to the development of ventilator-associated pneumonia, likely due to an increased risk of gastric reflux and subsequent aspiration. Several studies have demonstrated a benefit of semi-recumbent positioning (elevation of the head of the bed $>45^{\circ}$) in reducing ventilator-associated pneumonia.[314] Generally, patients were excluded from these studies if they could not tolerate an upright position due to hemodynamic instability or recent surgery. Furthermore, few data exists on non-ventilated patients.

Medications that increase gastric pH, such as H2 antagonists and antacids, allow for colonization of the upper gastrointestinal (GI) tract by potentially pathogenic organisms and may increase the risk for nosocomial pneumonia.

Sucralfate, an agent often used for stress ulcer prophylaxis, has limited effect on gastric pH and therefore may not increase the risk for pneumonia. Seven meta-analyses of over 20 randomized trials have investigated the impact of stress ulcer prophylaxis on risk of nosocomial pnuemonia in critically ill patients.[315] Four showed significant reductions in the incidence of pneumonia and three showed similar but non-significant trends toward reduced pneumonia in patients on sucralfate. A recent randomized trial, however, compared sucralfate to H2-antagonists and found no effect on pneumonia, but a significant increase in the risk of clinically important bleeding with the use of sucralfate.[316] This issue, thus, remains controversial with a priority being the identification of patients most likely to benefit from stress ulcer prophylaxis.

Selective digestive decontamination refers to sterilization of the oropharynx and GI tract in mechanically ventilated patients in hopes of preventing the aspiration of large numbers of organisms and subsequent pneumonia. Most evaluations of selective digestive decontamination have involved topical agents such as polymixin, aminoglycoside, and amphotericin. In some studies, investigators have also added short course IV therapy. There have been seven meta-analyses of over 40 randomized trials of selective digestive decontamination which have been recently summarized in a systematic review.[315] All seven trials showed significant reduction in the risk of ventilator-associated pneumonia with the use of SDD. However, it is unclear how routine use of selective digestive decontamination might affect antibiotic resistance patterns. While selective digestive decontamination is utilized more commonly in Europe, its use in the United States is limited primarily due to concerns about its possible effect on emerging antimicrobial resistance.[317] While potentially promising as a preventive measure, further study with careful evaluation of the impact of this strategy on antibiotic resistance is warranted.

9.2.7. Nosocomial Intravascular Infection. An accurate and practical surveillance system is essential for identifying the true scope of the problem and thereby allowing for implementation of effective strategies to reduce catheter-related bloodstream infections. Surveillance can provide the basis for an effective infection control program through the routine and orderly collection of data, subsequent analysis and timely reporting. In the SENIC study, hospitals with a high-intensity control program, regardless of the level of surveillance activities, showed a moderate 15% reduction in nosocomial bacteremia rates.[28] However, hospitals with a similar intensity control program but with at least a medium level of surveillance demonstrated a 35% reduction in nosocomial bacteremia rates. Proper choice of device, correct placement, and careful maintenance of intravenous systems are important in the control of infections at this site.[318] Care in prevention of contamination of the delivery system is important as is the documentation of the appropriate use of additives through dating and labeling. Recent guidelines for the prevention of nosocomial intravascular infections have been prepared by the CDC.[319] A recent study evaluated the impact of an evidence-based strategy including various infection control interventions (hand washing, using full-barrier precautions during the insertion of central venous catheters, cleaning the skin with chlorhexidine, avoiding the femoral site if possible, and removing unnecessary catheters to reduce intravascular infections).[320] This bundled intervention resulted in a large and sustained reduction (up to 66%) in rates of catheter-related bloodstream infection that was maintained throughout the 1.5-year study period.[320] Success in BSI reduction has been found with antibiotic-impregnated and antiseptic (e.g., chlorhexidine/silver-sulfadiazine)-impregnated catheters in several randomized trials.[321,322] However, conflicting data, questionable cost-effectiveness, and the potential for adverse events (e.g., anaphylaxis, emergence of drug resistance) have limited the widespread use of these novel devices. Current guidelines state that antibiotic/antiseptic-impregnated catheters should be used if the rate of infection is high despite adherence to other strategies.[323]

Important features for intravenous care are outlined in Table 10.

9.2.8. Antimicrobial Prophylaxis. The routine prophylactic use of antibiotics has not been demonstrated to control nosocomial infections in most sites and situations. The use of prophylactic antibiotics for surgical procedures is discussed in Section 9.2.5. Although prophylactic antibiotics, in the form of selective digestive decontamination, have been

Table 10. Guidelines for Intravenous Device Use[a]

   b. Observe daily
   c. Change set not more frequently than every 72 hour
5. Remove early
6. With sepsis, suspect iv site

[a]Modified from CDC guidelines.[200]

studied in the prevention of nosocomial pneumonia (Section 9.2.6), this practice remains controversial.

9.2.9. Immunization. Immunization for the prevention of bacterial nosocomial infection has not been exploited, largely due to the lack of effective vaccines. However, in other institutional situations pneumococcal and meningococcal vaccines have been tested and found successful. Both passive and active immunizations for control of nosocomial *Pseudomonas* infections in oncology and burn units have been investigated, but remain investigational.[324,325] Development of a vaccine against nosocomial *S. aureus* is also underway.[326]

9.2.10. Cellular and Transplantation Methods. Granulocyte transfusions have improved the response to infection in some leukemia patients with increased survival. This technique is limited by lack of sources for sufficient cells and recurrent concern about the ability to ensure their safe use in excluding occult microbial agents. Bone marrow transplantation is an increasingly successful technique, but one that requires great sophistication and resources. Hematopoietic growth factors, such as granulocyte and granulocyte–macrophage colony-stimulating factors, are increasingly being used in neutropenic patients. These growth factors stimulate the bone marrow to produce neutrophils, thereby shortening the duration of neutropenia following chemotherapy.

10. Unresolved Problems

10.1. Efficacy and Cost–Benefit Evaluation: Acute Care

The program of surveillance and infection control recommended by the CDC and mandated by governmental and accreditation agencies has benefited from the findings of the SENIC project.[28] The results showed a 32% overall reduction in nosocomial infection through application of a systematic infection control program. Since the data on which the study was based were gathered in 1970 and 1975–1976, the applicability to hospital practice two decades later remains open to some question. Medical care continues to change at a rapid pace with new technologies and shifts in practice, which have markedly altered the case mix and intensity of services offered in acute hospital care in the United States. As a result, an even higher portion of nosocomial infections may not be preventable by classic CDC methods, especially those from endogenous sources in highly immunocompromised patients.[261] Analyses have demonstrated nosocomial infection prevention and control programs to be not only clinically effective but also cost-effective,[78] particularly given the high cost of preventable nosocomial infections. Although continued studies evaluating the contemporary cost-effectiveness of infection control programs are needed, these programs appear well justified in the competition for resources in acute medical care.

10.2. Coordinated Programs

The many common features in nosocomial infection control and other quality improvement programs should be recognized. In US hospitals the quality assessment and improvement programs are commonly thought to include nosocomial infection control, risk management, monitoring of clinical outcomes, and care coordination. These programs are notable in using common data sources, applying common epidemiological methods, implementing similar analysis, sharing similar committee structures, and sharing similar goals of improved quality of patient care largely by avoiding increased nosocomial risk.[327] Recent emphasis on such issues as bioterrorism preparedness and patient safety, both closely related to infection control, highlights the need for the expertise of the healthcare epidemiologist in many arenas. The knowledge and skills of the healthcare epidemiologist also lend themselves extremely well to addressing many other issues at the forefront of patient care today. Knowledge of healthcare epidemiology is useful for drug use management, quality assessment, technology assessment, product evaluation, and risk management. In particular, application of healthcare epidemiology-based practices may offer much to the patient safety movement. These include establishing clear definitions of adverse events, standardizing methods for detecting and reporting events, creating appropriate rate adjustments for case mix differences, and instituting evidence-based intervention programs.[328,329]

10.3. Need and Efficacy in Developing Countries

With the exception of the WHO prevalence studies[4] and a few individual reports,[43,271] data on nosocomial infection risk in the developing countries are lacking. The potential for limiting loss of resources by preventing morbidity and mortality from nosocomial infections makes basic infection control appear even more critical in these countries, especially considering that the introduction of tools for sterilization, materials for disinfection and training in aseptic technique is relatively inexpensive. Indeed, while recent reports have noted the many challenges (e.g., administrative, financial) of establishing infection control programs in developing countries, the substantial impact of these programs has also been highlighted.[330]

10.4. Efficacy in Nonacute Care

Most studies of nosocomial infections have taken place in acute-care hospitals. A growing number of investigations are being reported in other healthcare settings such as nursing homes, rehabilitation, etc..[331,332,185,187–189] Nosocomial infection risk in other care settings, including ambulatory care, physician's office, and home care, is in the early stages of being studied and further characterized.[129,213,333]

10.5. Public Reporting of Hospital Infections

As noted earlier, mandatory reporting of healthcare-associated infection rates has become a reality. Although currently required in only a handful of states, mandatory reporting legislation is pending in over 20 additional states.[37] Although various professional organizations (e.g., APIC, SHEA, HICPAC) have all issued statements and published reports relative to the issue of mandated public reporting,[39,40] much uncertainty exists regarding the optimal approach. At this point, the specific healthcare-associated outcomes that are to be reported to the states are still being debated and differ across states. Furthermore, definitions of infections differ from state to state. In addition, there is currently no accepted method by which to risk adjust reported infection rates to account for differences in case mix across centers. Finally, the impact of public reporting on healthcare-acquired infections has not been evaluated.

ACKNOWLEDGMENTS

This chapter is a modification of the chapter entitled "Nosocomial Bacterial Infections" written by Louise M. Dembry, Marcus J. Zervos, and Walter J. Hierholzer, Jr. for the 3rd edition of the textbook "*Bacterial Infections of Humans: Epidemiology and Control*" (eds Evans AS, Brachman PS) published in 1998.

CHAPTER 27

Pertussis

Scott A. Halperin and Gaston De Serres

1. Introduction

Bordetella pertussis produces a single disease syndrome in man known as pertussis or whooping cough. The disease characteristically displays a protracted course measured in weeks to months, with the development of vigorous paroxysmal coughing often associated with vomiting and whoop. Complications include pneumonia; seizures; encephalopathy; hernias; rib fractures; and intracranial, retinal, and subconjunctival hemmorhage. At the turn of the century, it was a major cause of infant mortality worldwide. Largely due to immunization, the incidence of pertussis declined markedly during the middle of the 20th century; however, a resurgence of pertussis has been noted during the last several decades, even in countries with high immunization rates. The increased pertussis has mostly been observed in infants too young to have completed the primary immunization series and in adolescents and adults whose immunity has lapsed. In developing nations, pertussis continues to be a major child health problem.

2. Historical Background

The first recorded description of the disease dates from 1540 in England, and the first reported epidemic was in Paris in 1578.[1,2] Its absence from prior literature is curiously unexplained for a disease syndrome with such characteristic symptoms. Perhaps it attracted less attention than more devastating epidemic diseases such as plague and smallpox[1] or it may have been a disease of lower animals that became adapted to man.[3] This is supported by genomic analysis that found *B. pertussis* to be a derivative of *B. bronchiseptica*-like ancestors, a bacterium that affects animals.[4] It also has been suggested that smaller, isolated populations of the past with little contact among them could not sustain an organism with no carrier state or animal vector but productive of clinical immunity.[5] Identification and isolation of the responsible organism did not occur until the first part of the 20th century.[6] Because of poor understanding of the organism's biological anatomy as well as difficulties in propagation, attempts to develop effective vaccines were unsuccessful until the late 1930s. In the United States, whole, killed bacterial vaccines appeared to be of sufficient efficacy to warrant licensure and general use in young infants in the 1940s. Current federal regulations for vaccine production were established in 1953.[7]

Mortality from pertussis in the United States and other developed nations has declined throughout this century, even before the development and widespread use of pertussis vaccine and antimicrobial drugs.[8–10] Further decreases in death rates have occurred subsequently; the decline prior to the vaccine is not satisfactorily explained (see Section 5.1). But the fact that a decrease in mortality rates antedated widespread use of pertussis vaccine caused some authorities to question the necessity for the vaccine as a routine preventive measure for children,[11] particularly when there were allegations of severe adverse events against the whole-cell vaccines.

3. Methodology

3.1. Sources of Mortality Data

In the United States and other developed nations, the only sources of mortality information are published vital statistics. Case-fatality rates are inaccurate because the

disease is underdiagnosed and underreported.[12–14] Using capture-recapture methodology, it was found that one- to two-thirds of all pertussis deaths were not accounted for in the national disease reporting system.[13,14] In addition, it is likely that an uncertain proportion of fatal cases are incorrectly diagnosed as other types of bronchopulmonary infections or sudden infant death syndrome.[15]

3.2. Sources of Morbidity Data

While intermittent active surveillance provides a good estimate of the incidence of pertussis, continuous determination of the precise incidence of pertussis in the United States and elsewhere is not presently possible for four reasons. First, the disease is often not reported. Second, the diagnosis may often be missed, even for cases with classical symptoms.[16] Third, it is clear that there are mild, unrecognized forms of the disease, especially in vaccinated individuals and older children and adults with waning immunity. Fourth, a syndrome that is clinically indistinguishable from true pertussis may be produced occasionally by two other *Bordetella* species: *B. parapertussis* and *B. bronchiseptica*. Certain adenoviruses or other viruses as well other bacteria may produce the syndrome.[17–21] Therefore, except during clear-cut, laboratory-confirmed outbreaks in defined populations, estimates of the incidence of pertussis are unreliable because nearly 90% or more cases are not diagnosed or reported.[12,16] Because mortality occurs mostly in infants and because of the inverse relationship of case-fatality with age, mortality does not reflect the true incidence in all age groups.[17] However, incidence and mortality rates in infants too young to be vaccinated ($<$ 2 months of age) are probably good indicators of the overall transmission in the population.[22]

3.3. Surveys

Surveys to determine proportions of the population immune to pertussis are of limited value for the reasons noted above, because of failure to recall the disease or prior immunization, and because of the lack of one serological test that directly correlates with clinical protection.[23] However, high serological titers of pertussis toxin (PT) correlate well with a recent infection.[24,25] PT titers remain high for a mean of 4.5 months, ranging from 4 weeks to 1 year, after disease onset. Seroepidemiological surveys have been conducted to document the incidence of infection that may or may not have caused disease.

3.4. Laboratory Diagnosis

Although laboratory tests are not required to make the diagnosis when an individual presents with all the classical symptoms of whooping cough, laboratory confirmation is still recommended. In young infants, and adolescents and adults, manifestations of pertussis may not be typical and laboratory confirmation is essential.[26] Although clinical diagnosis has a higher predictive value during outbreaks, laboratory confirmation is still beneficial, particularly if interventions such as chemoprophylaxis of close contacts are being considered. Many clinicians consider absolute lymphocytosis of 10,000 or more lymphocytes/mm^3 to be strong circumstantial evidence of pertussis in a child with appropriate symptoms. The magnitude of lymphocytosis roughly parallels the severity of the cough. However, lymphocytosis may be absent in very young infants. Additionally, disease-induced lymphocytosis may be reduced in previously immunized or infected persons because of the presence of antibodies to PT, which is responsible for the lymphocytic response.

The single, time-tested, unequivocal diagnostic test for pertussis is isolation of the organism on culture from a nasopharyngeal swab[12,27] or, preferably, nasopharyngeal secretion aspirate.[28] The usual medium for isolation of this fastidious, slow-growing organism is either modified Bordet–Gengou agar enriched with 15% defibrinated horse blood (needs to be prepared freshly) or Regan–Lowe medium containing 10% horse blood (8-week shelf life). Swabs should be inoculated immediately; delay of as little as 1 hour reduces the likelihood of recovery of the organisms because the organism is sensitive to drying. When inoculation must be delayed, Regan–Lowe transport medium (half-strength) or phosphate-buffered saline with 1% Casamino Acids may be employed. The addition of methicillin or cephalexin to the culture medium enhances the likelihood of recovery of *B. pertussis* by suppressing the growth of other organisms, but may inhibit growth of some *B. pertussis* strains. Cultures should be incubated at 35°C in moist air and examined daily for 7 days. Colonies are small and pearly and display a small zone of hemolysis on blood-containing media. Further identification of colonies is achieved by agglutination with commercially available sera or by direct immunofluorescence.

In experienced hands, identification by culture is nearly 100% specific; unfortunately, the sensitivity of culture methods is far less, even in experienced hands. Fresh media are required and, after the fourth week of illness, recovery of the organism is much less likely. Other factors that reduce the likelihood of recovering the organism on culture include prior administration of erythromycin or other

macrolides, past pertussis immunization, delays in transport of the specimen to the laboratory, and increasing age.[26,27,29] Additionally, many clinical bacteriology laboratories lack experience in the identification of *B. pertussis* on culture due to the relative infrequency of the disease.

Considerable efforts have been made to develop more sensitive and specific means for the identification of *B. pertussis* in respiratory secretions.[27] The most promising approach is the polymerase chain reaction (PCR), which has been employed in the diagnosis of other infections due to hard-to-recover organisms.[30–32] In brief, this technique identifies gene sequences unique to the organism in question. For detection, the method requires very few organisms in the specimen and therefore is highly sensitive. PCR is more sensitive than culture and as specific if care is taken to avoid cross-contamination of specimens and the environment.[33,34] Although universally accepted methodology for PCR does not yet exist, many clinical laboratories are now routinely using PCR in addition to or, more recently, in place of culture. Continued standardization of methodology is required to avoid "pseudo-outbreaks" resulting from false-positive PCR tests.[35,36]

Examination of direct smears from nasopharyngeal swabs by direct immunofluorescence (DFA) appears in some, but not all, studies to be approximately as sensitive as culture, but unfortunately, in most laboratories, lacks optimum specificity.[26,27] For this reason, direct immunofluorescence should not be used routinely for the laboratory diagnosis of pertussis and is no longer accepted as laboratory confirmation by some national surveillance systems.

Serological diagnosis of pertussis is becoming increasingly important, particularly with the increased number of cases in adolescents and adults. Use of specific antigens of *B. pertussis* in the serological assays has improved the diagnostic specificity of the test. However, like PCR, standardized clinical assays are not available. Both IgG and IgA antibodies are elicited after natural infection, whereas IgA antibodies are less commonly found after immunization. Antibodies to pertussis toxin are most specific for *B. pertussis* infections since there are no other cross-reacting antigens. Although demonstrating a rising antibody level in paired sera is the gold standard, this is often difficult because of the late collection of specimens, particularly in adolescents and adults who do not present for health care early in the clinical course of the illness. Single serum criteria for the diagnosis of pertussis using comparisons to population normal values show promise and have been used successfully for nearly a decade in Massachusetts.[37] Efforts continue to establish single serum antibody thresholds for the serological diagnosis of pertussis.[24,25]

4. Biological Characteristics of the Organism

B. pertussis is a small, poorly staining, gram-negative organism that appears in coccobacillary form on fresh isolation. Older cultures display pleomorphism, ranging from filamentous forms to larger bacilli. *B. pertussis* can be distinguished from *B. parapertussis* and *B. bronchiseptica* by various biochemical characteristics, agglutination, and immunofluorescence.

B. pertussis produces a wide array of biologically active materials that are associated with its virulence and are under the control of a Bvg operon. Table 1 lists some of the important somatic antigens, toxins, and biological activities of *B. pertussis*. From what is known of the biological activities of several of these antigens, it is possible to hypothesize about their roles in disease pathogenesis.[5,38,39] Of prime interest is pertussis toxin, a component of all acellular pertussis vaccines. PT appears to participate in the pathogenesis of pertussis at several stages by enhancing attachment of the organism to respiratory cilia, interfering with host defenses,

Table 1. Major Components of *B. pertussis*, Their Actions, and Their Putative Roles in Pertussis

Component	Physiologic actions	Pathogenetic role	Role in immunity
Pertussis toxin	Lymphocytosis promotion Histamine sensitization Insulin stimulation Mitogenicity	Attachment to cilia Cell toxicity	Major antigen
Filamentous hemagglutinin	None known	Probably facilitates attachment to cilia	Probably contributes
Agglutinogens	None known	None known	Possible
Adenylate cyclase	Compromises cell metabolism	Compromises bacterial killing	Possible
Endotoxin	Many	Not defined	Probably none
Tracheal cytotoxin	Toxic to respiratory epithelium	Possible cell toxicity	Probably none
Heat-labile toxin	Dermonecrotic and lethal in animals	Unknown	Probably none
Pertactin	None known	Unknown	Major antigen
Fimbriae	None known	Attachment to cilia	Possibly major antigen

and causing cell toxicity. Antibodies to PT can be measured serologically following immunization or natural disease, including mild or inapparent infections.[40] In animal models, PT causes lymphocytosis, islet cell activation and increased insulin secretion, and sensitization to histamine; its role in human lymphocytosis is likely.[26] PT also has been shown to inhibit chemotaxis of neutrophils and inhibit oxidative responses in neutrophils and macrophages.[41,42] PT is an ADP-ribosylating toxin secreted only by *B. pertussis* although *B. parapertussis* also possesses the gene encoding the toxin.[43] PT is a typical A–B toxin composed of six polypeptides. The enzymatically active A component is comprised of a single S1 subunit while the pentameric B oligomer is responsible for toxin binding and comprises S2, S3, two S4, and S5 subunits. The exact role of PT in human disease is unknown since, other than lymphocytosis and clinical disease severity, all of the symptoms of whooping cough can be caused by *B. parapertussis* which does not produce PT.[44]

Filamentous hemagglutinin (FHA) appears to participate with PT in facilitating attachment of the organism to respiratory cilia and is a component of most acellular pertussis vaccines. Whether it has other activities in relation to humans is unclear. FHA is a large filamentous protein regulated by the Bvg operon. The molecule has multiple binding domains including an Arg-Gly-Asp triplet (RGD domain) that is important for binding to monocytes/macrophages and other leukocytes. FHA also contains a carbohydrate recognition domain (CRD) responsible for its binding to ciliated respiratory epithelial cells and a heparin-binding site responsible for adherence to non-ciliated epithelial cell lines and hemagglutlination.[26] The role of FHA, as with PT, in human disease has yet to be established; however, measurable antibodies to FHA develop following immunization and the disease, including mild or asymptomatic infection.[5,40]

Pertactin is a 69 kilodalton membrane protein proposed to play a role in bacterial attachment.[45,46] Pertactin is also under regulation of the Bvg operon and contains an RGD binding site as well as other motifs that are commonly associated with eukaryotic cell binding.[47] Although it has not been possible to confirm definitively the role of pertactin in binding in animal models and in vitro, serological studies during the acellular pertussis vaccine studies suggest that antibody to pertactin is the most important antibody in predicting protection from infection.[48,49]

Fimbriae are filamentous protein cell surface structures present on many gram-negative organisms, typically involved in bacterial adherence. Fimbriae in *B. pertussis* are regulated by the Bvg operon and are likely involved in bacterial adherence to host epithelial cells and monocytes. A definitive role for *B. pertussis* fimbriae in adherence has been difficult to demonstrate because of the multiplicity of adhesins present in the bacteria. However, studies in animal models and in human vaccine suggest an important contribution of fimbriae to protection.[48,49]

Strains of *B. pertussis* can be serotyped and studied epidemiologically by heat-labile agglutinogens, antibodies to which can be measured serologically in humans. Among the three species of the genus *Bordetella*, 14 such agglutinogens have been identified; those designated 1 through 6 are unique to *B. pertussis*. Agglutinogens 1, 2, and 3 are those most commonly identified.[39] The identity of the agglutinogens has not been established although pertactin, fimbriae, and lipopolysaccharide all have agglutinogen activity. High levels of antibodies to agglutinogens (agglutinin antibodies) are associated with protection from infection after immunization with whole-cell pertussis vaccines in the original efficacy studies over 50 years ago.[50]

Adenylate cyclase is a component of the organism, largely somatic, that contributes to overcoming host defenses and, perhaps more importantly, facilitates cellular damage by inducing wasteful cell hypermetabolism.[38] Whether antibodies to adenylate cyclase, which is antigenic, contribute to clinical immunity is unknown.

Like other gram-negative bacteria, *B. pertussis* produces a lipopolysaccharide endotoxin that is mitogenic and pyrogenic and can induce tumor necrosis factor production by macrophages. The LPS of *B. pertussis* differs from those of *Enterobacteriaceae*, and its role in pathogenesis of the disease has not yet been elucidated.

There are several other components of *B. pertussis* that may well play roles in disease pathogenesis.[5,38,39] Among these are tracheal cytotoxin, which probably damages tracheal and bronchial epithelium, and a heat-labile toxin that is dermonecrotic or lethal and cytotoxic for bronchial epithelium in animal models.

5. Descriptive Epidemiology

The epidemiology of pertussis has been dramatically modified by immunization. However, even prior to widespread immunization in highly developed countries such as the United States and currently in less developed countries, pertussis has displayed distinctive epidemiological characteristics.

5.1. Prevalence and Incidence

Pertussis is a reportable disease. Because it is very contagious and is associated with mortality in infants and young

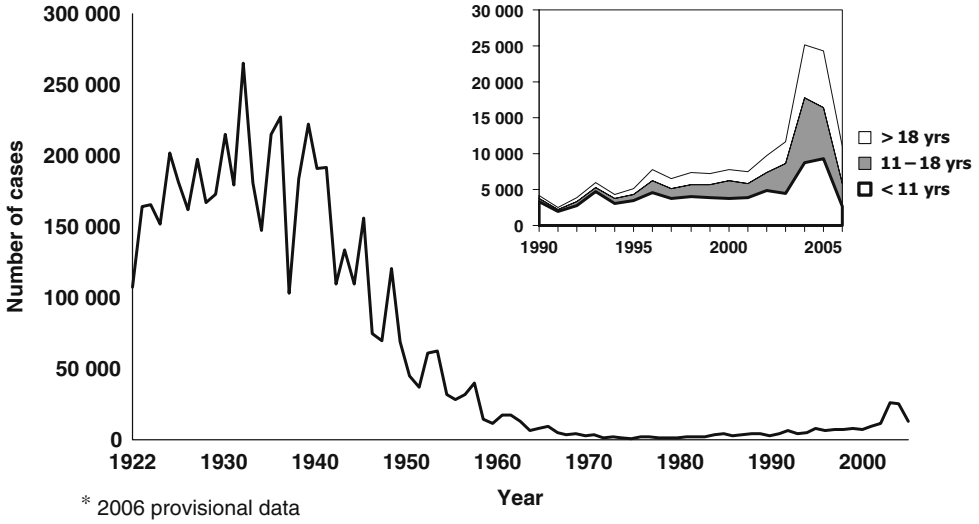

Figure 1. Reported number of pertussis cases in the United States, 1922–2006 (Source: Centers for Disease Control and Prevention (CDC) (75)).

children, it is important to make every effort to establish the diagnosis and report probable and proven cases to local health authorities. As noted above (Section 3.2), pertussis is vastly underreported, for the reasons that the diagnosis is often missed or is equivocal, medical care may not be sought, and some physicians may not be convinced of the importance of reporting. Since 1976 when pertussis notifications in the United States were at an historic low with 1,010 cases, reported cases have gradually increased to 25,827 in 2004, its highest count since 1959[51] (Figure 1). The incidence in 2004 was 8.9 per 100,000 and declined slightly the following 2 years.[52] After varicella, pertussis is currently the most frequently reported vaccine-preventable disease. This large increase is too great to be accounted for by population growth. How much this increase is an artifact attributable to augmented reporting because of better diagnostic procedures, enhanced awareness due to the alleged risks of pertussis vaccine being dramatically portrayed in public media, or other factors is unclear. This increase does not seem attributable to a decline in vaccine coverage. According to the National Immunization Survey (NIS), use of DTaP, DTP and DT was 66.3, 33.1, and 0.3%, respectively in children $\leq$18 months for 1998–1999.[53] For 2004, NIS reported that 95.9% of children 19–35 months of age had received $\geq$3 doses of DTaP, DTP, and DT.[54] While the pertussis increase affected all age groups,[55] it is remarkable in that the incidence in adolescents and adults has increased proportionately more than in young children.[51,56,57] As almost all adolescents and adults have been vaccinated during childhood, waning of vaccine-induced immunity is believed to be the main factor explaining their vulnerability.

While reported incidence in adults is still low, studies in adults with cough found that 12–32% had serologic, PCR, or culture evidence of pertussis infection.[58–69] Active surveillance for pertussis in coughing adolescents and adults found the incidence of laboratory-confirmed pertussis to range from 176 to 507 per 100,000 person-years.[64,70,71] Individuals with clinical disease represent only a part of all infected persons. Sera collected between 1991 and 1994 by the Third National Health and Nutrition Examination Survey (NHANES) were analyzed retrospectively and showed a rate of infection of 2,890 per 100,000 in individuals aged 10–49 years, with more frequent infections in adolescents and adults around 40 years of age.[25] A similar high rate of infection was also found in the United Kingdom.[72] A serological survey in Europe showed that rates of infection were highest in adolescents in countries with high vaccine coverage, whereas in countries with low coverage, infections were highest in children $<$10 years of age.[73]

Similar to incidence, reported mortality has also increased in the United States since the 1980s. There were 77 reported deaths between 1980 and 1989 and 91 between 1990 and 1999, for a mean annual number of 7.7 and 9.1, respectively.[74] This increase continued after 2000, and 27 deaths were reported in 2004.[75] Although it is clear that case-fatality rates from pertussis are inversely related to age, precise rates are difficult to determine, largely because of underreporting of the disease. Moreover, mortality rates in the developed world decreased in this century independent of immunization or any other form of specific intervention.[8,9,76,77] Direct evidence of the decline in mortality is limited to areas with optimum reporting of cases as

well as deaths, such as Providence, Rhode Island,[78] where case-fatality rates steadily declined from 1.36% in 1930–1934 to 0.24% in 1945–1949. Unfortunately, most information related to age-specific case-fatality rates is derived from children hospitalized with pertussis and thus is subject to the biases of such data. However, because almost everyone born between 1900 and 1949 experienced the disease during childhood, the decline in pertussis mortality in the developed world must be attributed to a decrease in case-fatality rates rather than reporting bias. For example, in the United States, annual deaths attributed to pertussis in children <1 year of age were 4.34 per 1,000 for the years 1900–1904; for 1935–1939, before specific measures such as immunization and antimicrobial therapy were developed, the annual death rate in this age group had declined 70% to 1.30 per 1,000.[9]

The reasons for this decline are unclear, but may be a consequence of a number of factors. These include better nutrition, the decline of debilitating conditions such as diarrheal diseases that compromised survival, quarantine of recognized cases, better supportive care, and decreasing birth rates that resulted in proportionately fewer infants being exposed to affected older siblings. In addition to those factors that predated the introduction of vaccination, mortality has also been significantly reduced by vaccination. The lowering of vaccine coverage pertussis in the United Kingdom during the 1970s was followed quickly by large outbreaks and numerous deaths.[79,80] When vaccine coverage increased again, the mortality plummeted.

There is also little doubt that advances in technologies available in intensive care units have resulted in the survival of the majority of infants critically ill with pertussis, many or most of whom would have otherwise succumbed. However, in less developed parts of the world, pertussis persists as a major cause of infant mortality. For 2002, the World Health Organization (WHO) estimated that 294,000 children died of this preventable disease prior to their fifth birthday.[81] While deaths in elderly individuals are rarely reported, pertussis caused an outbreak in a monastery where 53% of the 55–94-year-old residents had laboratory-confirmed pertussis and 10% of them died from intracranial bleeding while they were symptomatic for pertussis.[67] This outbreak was unusual in its severity but, with an increasing number of adult cases, it is possible that mortality will become an issue.

5.1.1. High-Risk Groups. Pertussis spreads easily in every group of the population but its incidence is highest in unvaccinated individuals who failed to be vaccinated, perhaps because they were too young or because they refused vaccination. The other group at high risk is broader and includes people in whom vaccine-induced immunity has waned.

For death, three risk factors are well identified: lack of vaccination, very young age, and prematurity. Nearly 90% of reported deaths occured in unvaccinated children.[74,82] Death occurs in the first months of life and is rare ($\leq$10%) after the first year of life. While 49% of the deaths occurred in children <2 months of age between 1980–1989, these children accounted for 66% of deaths in the 1990s.[74] Prematurity has also been associated with increased mortality. Among US children who died from pertussis in the 1990s, 51% were born at <37 weeks of gestation and 29% were born at <35 weeks. When limited to children with onset of pertussis between 2 and 11 months, the data show that 48% were born at <35 weeks.[74]

5.2. Epidemic Behavior and Contagiousness

Pertussis is both an endemic and an epidemic disease. In the absence of immunization, essentially no child escapes pertussis.[23] Indeed, during both World War I and World War II, pertussis, in contrast to other childhood contagious diseases, was rarely seen in military personnel, suggesting high prevalence of naturally acquired immunity.[1,78] Secondary attack rates in susceptible family members may reach 90% or more[23,83] and have been recorded as 100% in some studies.[17] There is, however, evidence that mild atypical cases occur in fully susceptible children.[78,84,85] Few data from the pre-vaccine era exist regarding transmission in school settings. However, one study examined an outbreak in an elementary school in Rochester, New York.[86] Excluding children with a past history of pertussis and those with exposure to a sibling with the disease at home, 40 (42%) of 95 school-exposed children developed the disease. Among presumably susceptible children, rates of whooping cough were higher in the lower grades, indicating that some of the older children had experienced forgotten or unrecognized infections in the past. While institutional[87–89] and local outbreaks continue to occur like in Cincinnati,[90] Chicago,[91] Massachusetts and Maryland,[37,92] Vermont,[93] Canada,[94,95] and elsewhere,[91,96] regional or statewide outbreaks have been more frequent than in the 1980s.[56,96]

The disease appears to be most contagious during the catarrhal stage (the first week of symptoms) and declines so that, as the paroxysmal cough begins to wane, infectivity generally disappears. Early studies in unvaccinated children found that a majority (62–83%) with pertussis had a positive culture up to 21 days after onset of symptoms.[97,98] During the fourth and fifth week of disease, the proportions decreased to 32–39% and 11–15%, respectively . Other more recent studies including mostly unvaccinated children confirmed that culture remains positive in about one-third of

cases during the fourth week and in more than 10% during the fifth week.[99,100] The proportions were not very different in vaccinated cases.[100] However, contagiousness of vaccinated cases is reduced as compared to unvaccinated ones.[101] So even if contagiousness is much lower 3 weeks after the onset of disease, a percentage of cases can still transmit after this period.

While it is still uncertain whether pertussis can be transmitted by individuals without overt disease, asymptomatic vaccinated individuals can be culture-positive for pertussis but the number of bacteria is much lower than in symptomatic cases.[102] These individuals, as well as those immunized in young childhood who experience a mild, clinically unrecognizable disease in adolescence or young adulthood, may serve as a source of exposure. Currently there is no evidence of a long-term asymptomatic carrier state.

5.3. Geographic Distribution

The distribution of pertussis is worldwide, though clearly modified by immunization and other poorly defined social, economic, and nutritional factors. The number of cases of pertussis occurring worldwide cannot be estimated with accuracy. Reported incidence rates vary among different nations; the low incidence in some countries may represent poor case reporting, herd immunity from preceding outbreaks, or high levels of immunization. The highest rates occur in those developing countries where immunization programs are inadequate. However, as measured by death rates from pertussis, the incidence must be declining as a consequence of the Expanded Programme on Immunization.[81,103]

5.4. Temporal Distribution

Pertussis outbreaks occur at any time but are perhaps more frequent in the summer. Pertussis is reported more often in summer in younger children.[96] In the past this was believed to be due to increased contacts between young children during warmer months. In persons aged 5–19 years, the peak of the season is between October and December[56] or even during winter months.[94] Different seasonal patterns have also been reported from various countries.[104]

Outbreaks occur every 3–5 years; in isolated areas, intervals of relative freedom from pertussis sometimes extend beyond 6 years.[78,105] While the incidence of disease has decreased with immunization programs, the interepidemic period has not increased, suggesting that the rate of infection in the population has not been reduced substantially.[23]

5.5. Age

Since the introduction of vaccination, there has been a noticeable shift in the age distribution of reported cases of pertussis. For the years 1935–1939, prior to the availability of pertussis vaccine, data from ten states indicated that, for whites, about half of all cases of pertussis were reported in 5–14-year-old children;[8] for blacks, this proportion was lower (20–40%), with the preponderance of cases occurring before 5 years of age. Less than 15% of cases in whites occurred before 1 year of age, but the proportion of cases in infancy among blacks was nearly twice that in whites, probably for socioeconomic reasons.[8] The proportion of reported cases in persons 15 years and older was $<2\%$ in the late 1930s.[8]

Widespread use of pertussis vaccine during the past five decades has been associated with a marked decline in reported cases and with a striking shift in the proportions of cases in various age groups. For 1980–1989, 50% of cases were reported in infants in contrast to 12.5% in 2004[51,96] whereas these proportions in children 5–14 years old were 17 and 30%, respectively. The greatest change, though, was in persons 15 years and older where the number of cases increased from 12 to 41% during the same period.

Infants too young to have been vaccinated have the highest incidence of pertussis (Figure 2). While the incidence in infants 5 months and older remained fairly stable, it increased substantially in younger infants since the mid-1990s. During the same period, incidence has also increased in older children and adults, with the incidence of pertussis in children and adolescents 10–19 years of age now surpassing that of younger children (Figure 3). The cause of this generalized phenomenon is unclear but may be an artifact of better diagnosis and enhanced reporting or waning immunity (see Section 7.2).

5.6. Sex

Although both sexes are presumably equally affected, pertussis is unusual in that, inexplicably, the disease is more often reported in females. It may be that the smaller larynx of female infants places them in greater jeopardy of severe disease. While females formerly exhibited higher mortality rates, in the 1990s, deaths were equally divided between sexes.[74]

5.7. Race/Ethnicity

Death rates were formerly higher in blacks[8] but Hispanics have been the most affected group in recent years;[74] it is

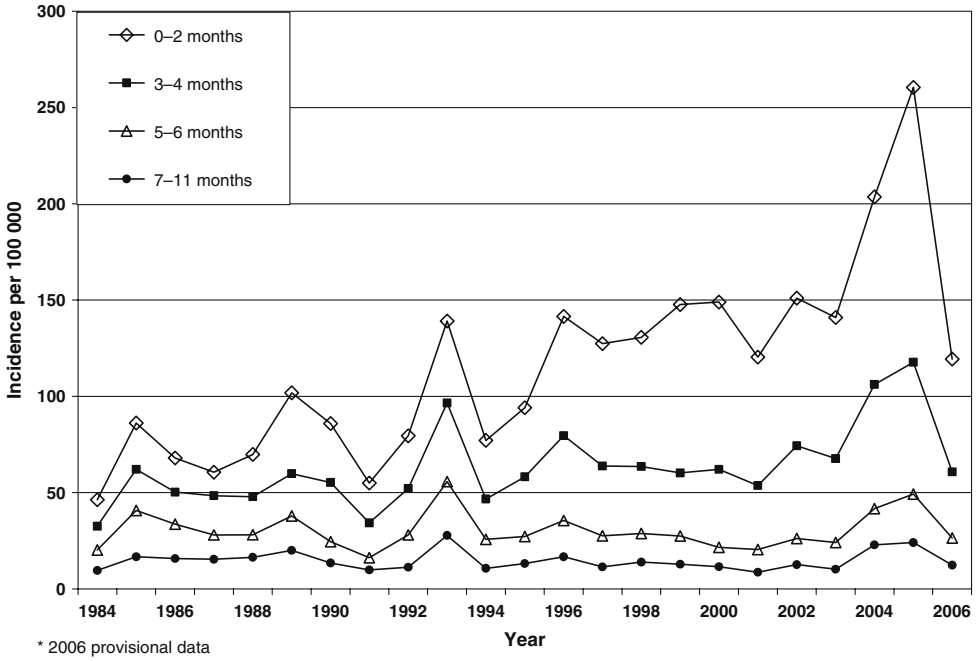

Figure 2. Reported incidence per 100,000 of pertussis among infants in the United States, by month of age, 1984–2006 (Source: CDC (75)).

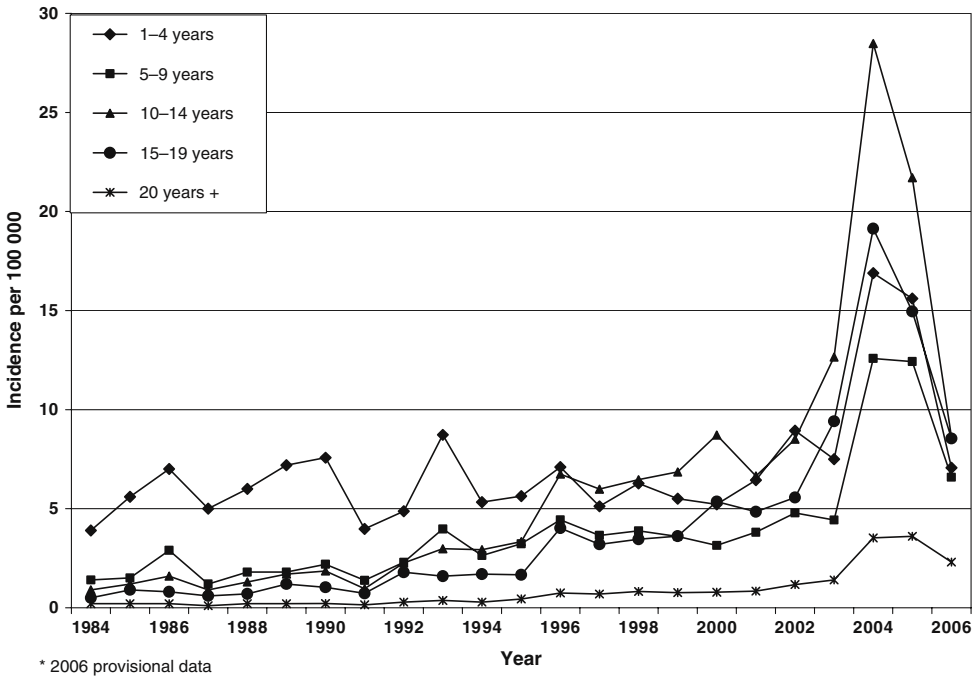

Figure 3. Reported incidence per 100,000 of pertussis by age groups in the United States, 1984–2006 (Source: CDC (75)).

likely that these higher rates are attributable to lower vaccine coverage and socioeconomic and other factors, rather than to race.

5.8. Other Factors

Mortality rates are higher in lower socioeconomic groups, probably because of exposure earlier in life due to crowding and close contact. However, case-fatality rates are also inversely related to socioeconomic status for reasons that are unclear;[19] access to health care and nutrition may play roles. In contrast to many infectious diseases, mortality from pertussis has been higher in rural than in urban areas.[78]

6. Mechanisms and Routes of Transmission

Pertussis is transmitted via close contact by droplets. It is highly contagious; indeed, up to 90% of susceptible family contacts will develop clinical disease from an index case in the household.[2,83,106–109] There is no evidence of spread by other routes such as airborne droplet nuclei, fomites, or dust.

7. Pathogenesis and Immunity

7.1. Pathogenesis

The pathogenesis of the disease, better defined in recent years, comprises attachment of the organism to tracheal and bronchial cilia, evasion of host defense, induction of local tissue damage, and production of systemic manifestations. Cellular invasion occurs but systemic dissemination does not. Adherence is mediated by multiple adhesins, including pertussis toxin, filamentous hemagglutinin, pertactin, fimbriae, and others (lipopolysaccharide, BrkA). The redundancy of the adhesins has made it difficult to determine which is of primary importance. Evasion of host defenses is achieved by pertussis toxoid and adenylate cyclase toxin which inhibits migration of lymphocytes and macrophages and interferes with neutrophil phagocytosis, respectively. Local tissue damage results from tracheal cytotoxin, dermonecrotic toxin, and lipopolysaccharide.[26] The cough appears to be due to local tissue damage and interference with normal mechanisms of bronchial toilet; mucoid secretions accumulate and are responsible for ineffective, repetitive, paroxysmal coughing and, ultimately, for varying degrees of bronchial obstruction, atelectasis, and bronchopneumonia.[2] However, the duration of symptoms exceeds the duration of the local damage so other unknown toxins or mechanisms may contribute to the clinical manifestations. Bronchopneumonia is the most frequent serious complication of pertussis. In older children, it most often results from invasion by nonspecific respiratory flora or other respiratory pathogens such as *Streptococcus pneumoniae*. In very young infants, invasion by *B. pertussis* itself with a primary pertussis pneumonia is common.[82] Pneumonia occurs in up to 10% of infants and the elderly with pertussis and less frequently among older children, adolescents, and young adults.[110–112] Other systemic manifestations such as lymphocytosis and hyperinsulinism resulting in hypoglycemia are caused by the actions of pertussis toxin.

A major complication of pertussis is encephalopathy, varying in manifestations from short-lived convulsions to intractable seizures, coma, and permanent cerebral damage.[9,17] The mechanism of pertussis encephalopathy is unclear. The assumption that encephalopathy results from the direct effects of one or more of the toxins of *B. pertussis* no longer appears tenable, and instead it is likely that anoxia and, in some instances, cerebral hemorrhages are responsible.

The experience of contagious disease hospitals and institutions for the handicapped in the past indicate that pertussis encephalopathy is far from rare,[17,113,114] but few data are available. One estimate may be derived from cases reported from the contagious disease hospital that served residents of Brooklyn, New York, in the 1930s.[115] The childhood population of Brooklyn can be approximated from birth records and, assuming that every child in Brooklyn experienced pertussis, the incidence of severe encephalopathy was approximately 1 in 22,000 cases. A more precise estimate, made by the British National Childhood Encephalopathy Study (NCES), approximated a frequency of 1 in 11,000 cases.[116] More recently, in hospitalized cases of pertussis, seizures have been reported in 0.8–2.0% and encephalopathy in 0.1–0.4% of cases.[53,111]

7.2. Immunity

The duration of immunity after clinical pertussis is not known; although previously thought to be lifelong, this is now known not to be the case. In recent years, several well-documented series of pertussis in adults have been reported[117–123] including instances of recurrent, laboratory-confirmed cases. In many instances, these illnesses are mild and atypical but classical pertussis with complications can occur.[124,125] It appears that pertussis in adults is more common than formerly appreciated and may occur in persons who experienced the disease in the past as well as in those who were actively immunized as children.[26] The increased rates of disease in adults may be the result of both better recognition and an actual increase in rates in older persons.

If there is a true increase, it is tempting to hypothesize that immunity, whether induced by pertussis or by the vaccine, has been more apt to wane in recent decades due to the present infrequency of exposure to the infection and the consequent lack of repeated, casual "streetcar" boosters.[119] Whatever the reason, it is apparent that pertussis in adolescents and young adults is a problem of some importance, particularly because such persons may constitute a reservoir of infection and a source of transmission to others, including young infants.[117,119,120,122]

The mechanisms of clinical immunity to pertussis have escaped definition for many years, and only in the last two decades has much progress been made. This progress has resulted from laboratory studies that have defined much better the components of the organism and from new methods of measuring antibodies serologically. Several antigens have been identified that appear to be important in the pathogenesis of pertussis and in addition induce antibodies, one or more of which may provide clinical protection against the illness (see Section 4). One of these is PT, which appears to be the major antigen that produces immunity in the mouse protection test, long used for laboratory evaluation and standardization of pertussis vaccine. Pertactin has also been identified as an important antigen that best correlates with protection after immunization.[48,49] FHA also may be important not only in disease pathogenesis but also for induction of clinical immunity. FHA is thought to facilitate attachment of *B. pertussis* to respiratory cilia; however, in the acellular pertussis vaccine efficacy trials, FHA did not appear to contribute to increased protection.[48,49] Fimbriae have also been shown to be important in immunity after immunization, particularly in the protection against mild illness.[126] The agglutinogens may relate to the induction of clinical immunity as well; three of them appear to be of consequence. Their relation to disease pathogenesis is uncertain, but general studies in the past have suggested correlation between clinical immunity and levels of antibody against agglutinogens.[83] Further, there is some indication that a mismatch between the specific agglutinogens in pertussis vaccine and those of circulating *B. pertussis* strains is associated with diminished vaccine efficacy.[127]

There is a probable role for secretory IgA-mediated immunity;[128] IgA antibodies against specific pertussis antigens can be detected in the saliva and nasopharyngeal secretions after pertussis infection, although not usually after immunization. In addition to humoral immune responses, cell-mediated immune responses to pertussis antigens have been measured after human infection and in animal models. A Th1 response to PT, FHA, and pertactin occurs after natural infection and after immunization with the whole-cell vaccine. A Th2 response occurs primarily after immunization with acellular pertussis vaccines.[129,130] The relative contributions of humoral and cell-mediated immunity in protection against infection and recovery from infection has yet to be elucidated.[131]

8. Patterns of Host Response

8.1. Clinical Features

The incubation period of clinical pertussis is usually 7–10 days and rarely longer than 2 weeks. The first week or two of the illness is called the catarrhal stage, because initial symptoms of the disease are nonspecific, including mild but gradually increasing cough, nasal symptoms suggestive of a cold, slight fever, and some anorexia.

As the catarrhal stage progresses, the cough increases so that severe spells of coughing with the characteristic whoop appear about 2 weeks after onset, marking the beginning of the paroxysmal stage. The paroxysmal cough results from an inability to expel tenacious mucus; the whoop is created by vigorous inspiration through the glottis at the end of the paroxysm. Paroxysms may occur repeatedly and may be initiated by eating, drinking, talking, crying, examination of the throat, or even by hearing another individual cough (such as occurs in a hospital where there are other children with pertussis). During paroxysms, cyanosis may occur. Repetitive post-paroxysmal vomiting may be sufficiently prolonged to cause substantial weight loss. Fever is usually low and may be throughout the course of pertussis in the absence of secondary infection. Subconjunctival and cerebral hemorrhages and epistaxis, umbilical and inguinal hernias, and rib fractures may be seen. Convulsions, with or without encephalopathy, and pulmonary complications occur during the paroxysmal stage.

In classic pertussis, the duration of the paroxysmal whooping stage is 4 or more weeks, with increasingly frequent paroxysms for 1–2 weeks and gradual subsidence and ultimate disappearance of the whoop thereafter as the patient enters the convalescent stage. Cough may persist for some weeks into the convalescent stage, and exacerbations may occur for up to 1 year if an intercurrent respiratory infection occurs. Mortality from pertussis is inversely related to age. The case-fatality rate in hospitalized infants is approximately 1%; after 5 years of age, it is negligible.

The major causes of mortality appear to be pulmonary complications including overwhelming pertussis pneumonia and pulmonary hypertension, with some contribution from encephalopathy and other neurological complications.[82] Secondary or intercurrent affections, such as otitis media,

mastoiditis, inanition, and diarrhea, undoubtedly contributed to mortality in the past in the United States and continue to do so in developing countries.

Permanent neurological sequelae from pertussis, especially from pertussis in infancy, undoubtedly occur.[114–116] More subtle intellectual or behavioral abnormalities also may result in some instances.[113,132] Given the high mortality after severe pulmonary infection and the failure of intensive therapies such as extracorporeal membrane oxygenation to alter the outcome,[82] long-term pulmonary damage has not been described.[133,134]

8.2. Diagnosis

The diagnosis of the full-blown pertussis syndrome is readily made on clinical grounds by most clinicians who have had experience with the disease. The protracted course, paroxysmal coughing, and whoop are unmistakable. A history of exposure or knowledge of other cases in the area is of help.

Immediate support for the diagnosis of pertussis frequently may be obtained from the leukocyte count. Absolute lymphocytosis, often striking, parallels the severity of the cough, but is said to be less characteristic in young infants or adolescents and adults.[19] A definitive diagnosis may be established in two ways. First, recovery and identification of *B. pertussis* by culture or PCR of respiratory secretions is definitive (see Section 3.4). However, isolation on culture is not accomplished easily and care must be taken to avoid cross-contamination of PCR specimens during collection and specimen processing. Identification of the organism in respiratory secretions by fluorescent-antibody techniques is compromised by frequent false-positive tests[12,27] and is less sensitive. Serological testing for the diagnosis of pertussis has been improved considerably by testing paired acute and convalescent sera by enzyme-linked immunosorbent assays (ELISA).[12,27,120] Using this technique, antibody responses to PT, FHA, pertactin, and fimbriae of *B. pertussis* can be measured, and the method is highly sensitive and specific.[12,27,37,40,120,128] Although IgM responses to infection (and immunization) occur, the rise and fall of these responses is usually too rapid to be of diagnostic utility. Potential limitations of the ELISA method include failure to recognize an IgG response in a previously immunized individual because the rapidity of anamnestic responses may result in a rise in IgG antibodies before the acute serum is obtained. In such instances, infection may be recognized by a primary IgA response because IgA antibodies are not induced by immunization.[128] More recently, serum IgA responses against several antigens have been demonsrated after acellular pertussis vaccine. It also has been shown that single convalescent ELISA serum antibody levels that exceed the mean of a control population by three standard deviations are of diagnostic value when timely acute serum samples were not obtained.[37,40,120,121] Additional studies suggest that exceeding a population-derived level of anti-PT antibody can be used to diagnose pertussis as long as it has been at least 3 years since a previous dose of acellular pertussis vaccine.[24,25] Treatment of pertussis with erythromycin or other macrolides appears to have little or no effect on antibody responses.[135]

Because no absolute serological correlate of protection has been identified for pertussis, a standardized case definition was established to measure the efficacy of candidate acellular pertussis vaccines. The most widely accepted case definition established through the World Health Organization defined typical pertussis as 21 or more days of paroxysmal cough plus one or more of the following: a positive culture; a significant rise in IgA or IgG antibodies to FHA, PT, or fimbriae 2 and 3; or household exposure to a culture-positive case within 20 days before or after disease onset in the subject in question.[136] This definition is associated with high specificity but lower sensitivity. For surveillance purposes where higher sensitivity is desired, even at the expense of specificity, the Centers for Disease Control and Prevention (CDC) has defined pertussis clinically as a cough illness lasting at least 2 weeks with one of the following: paroxysms of coughing, inspiratory "whoop," or post-tussive vomiting, without other apparent cause (as reported by a health professional).[137]

9. Control and Prevention

In the absence of widespread immunization, outbreaks of pertussis cannot be prevented and control is difficult. Rates of transmission to susceptible households may be 90% or higher; in classroom situations, up to 50% of susceptible students in the same room may acquire the disease following exposure to an infected child (see Section 5.2).

9.1. Isolation

Isolation or quarantine of children with clinical whooping cough is of limited value in controlling spread of the disease, for the reason that children in the catarrhal stage, before the characteristic whoop appears, are quite infectious.

To prevent transmission, recognized cases should be excluded from school and contact with other children for 5 days after beginning effective antimicrobial treatment. The

carrier state in pertussis has not been demonstrated; if such exists, it is doubtful that it plays an important role in transmission because of the lack of associated cough. Milder forms of the disease, which occur in partially immune individuals, probably play a role in transmission (see Section 6).

9.2. Antibiotics

Pertussis is relatively insusceptible to antimicrobial therapy clinically. Although the organism is susceptible in vitro to various antimicrobial drugs effective against gram-negative organisms, in vitro susceptibilities do not correlate with clinical effectiveness. Macrolide antibiotics including erythromycin, clarithromycin, and azithromycin are effective in eradicating the organism from the nasopharynx within 5 days and may therefore reduce transmission. Duration of therapy with erythromycin has generally been recommended for 14 days, although 7 days has been shown to be equivalent;[138] 5 days of azithromycin was equally effective.[139] Antibiotic therapy does not have a substantial effect on the clinical course of the disease unless given early during the catarrhal phase.[135,138–143] By the time the patient is well into the catarrhal stage or has begun to whoop, benefit is not expected. Because exposure is often unrecognized and because the disease is rarely suspected during the catarrhal stage, antibiotics do not comprise a satisfactory approach to disease control.

Macrolides administered as chemoprophylaxis to patients' contacts have been used for decades, but there is great controversy over the efficacy of this intervention.[142] While epidemiological studies found some benefit,[143–145] randomized clinical trials did not.[140] Administration of chemoprophylaxis very early after exposure is probably key to obtain some results, but this is unfortunately rarely possible given the delay between onset of disease and the diagnosis of pertussis in the index case. Given the uncertainty about its efficacy, Canada and the United Kingdom restricted chemoprophylaxis mostly to situations involving risks of pertussis in an infant. In the United States, chemoprophylaxis is used for broader indications. There is clearly a need for better evidence regarding the efficacy of chemoprophylaxis.

9.3. Passive Immunization

Passive protection of exposed, susceptible individuals was attempted in the past with varying results. In the late 1930s, convalescent and hyperimmune sera were administered to susceptible children exposed within the same household. In one small controlled study, protection appeared to be as high as 70%.[106] Subsequently, pertussis IgG, prepared from human or rabbit sera, was employed with negative results.[148] More recently, reports from Sweden and Japan have indicated that human hyperimmune globulin containing anti-FHA and anti-PT effectively ameliorated the course of pertussis,[147, 148] and a study in the US suggested benefit with an anti-PT hyperimmune intravenous immunoglobulin.[149] However, an efficacy study with the product was terminated early because the product was no longer available; no benefit was apparent at the time the study was ended.[150]

9.4. Active Immunization

Prior to World War I, ill-controlled, hit-or-miss attempts were made to develop an effective pertussis vaccine, with inconclusive or uninterpretable results. By the mid-1940s, whole-cell killed pertussis vaccine was widely used in the United States. Current criteria for standardization of the vaccine in the United States were established in 1953 by federal regulation.

There is little question that most properly immunized children are protected against pertussis on exposure.[39,151] However, the proportion of children actually protected when intimately exposed, such as in the home, is less than 100%.[152] The severity of the disease in previously immunized children is usually milder. Estimates of vaccine efficacy in studies of exposed immunized and unimmunized children vary remarkably because of differences in study methods and in ascertainment, particularly in relation to recognition of infection versus clinical disease, as well as differences between various whole-cell vaccines.

Concerns about the safety of whole-cell vaccines led to the development of acellular pertussis vaccines. Three general types of reactions have been attributed to whole-cell pertussis vaccines. The first of these comprises mild local reactions at the site of injection and slight systemic reactions, such as fever and malaise, as observed following receipt of most vaccines. These are usually of no concern. A second group of reactions includes two that are quite disturbing but appear to be without permanent sequelae. These include incessant, inconsolable crying and a strange, shock-like syndrome following injection in young infants. The crying is very likely due to pain at the site of injection. The cause of the shock-like hypotonic-hyporesponsive episodes has not been identified but is also likely due to a pain response. Though these episodes are frightening, death or other sequelae in association with them has not been described. The third group of events includes those related to the central nervous system. These events range from what appear clearly to be simple febrile convulsions without sequelae[153] to severe encephalopathy with permanent brain damage or

death. Although it is clear that pertussis vaccine is the antigen in DTP (pertussis vaccine combined with diphtheria and tetanus toxoids adsorbed) that contributes most to fever and local reactions, it has not been shown that it is the component primarily responsible for the other phenomena.

A 1981 study provided somewhat more precise information about the frequency of the first two groups of side effects.[154] In this study, infants and children who received a total of 15,752 inoculations of DTP and 784 of DT (diphtheria and tetanus toxoids absorbed) were followed for 48 hours. Local and systemic reactions, including fever, were considerably more frequent following DTP than DT. Nine children experienced short seizures following DTP; all but one episode were associated with fever. Nine other children had hypotonic–hyporesponsive episodes. Thus, each of these reactions occurred at a rate of 1/1,750 injections (95% confidence interval: 1/925 to 1/3,850). However, attribution of these two more worrisome types of reactions solely to the pertussis component of DTP was not feasible because too few immunizations (784) with DT were monitored to permit comparison.

Estimates of rates of post-pertussis-vaccine encephalopathy have ranged from 1/50,000 to 1/300,000 or more;[155] subsequently, a well-designed study that controlled for background rates of encephalopathy suggested that serious neurological reactions occur following 1/110,000 injections and that about one-third of children so affected incur sequelae that may be evident 10 years later.[116,156] However, there are doubts about the precision of this rate, and indeed it has been concluded by the investigators that the results show that pertussis vaccine produces permanent brain damage very rarely or not at all.[156] Instead, it may be that the majority, if not all, of the instances of alleged pertussis vaccine encephalopathy represent either coincidence or the precipitation of inevitable manifestations of pre-existing disorders by the well-known systemic effects of DTP. Most authorities have concluded that permanent brain damage as a result of DTP is either a myth or is so rare that it cannot be differentiated from coincidence. Although occasional reports have suggested that DTP may precipitate the sudden infant death syndrome on rare occasions, several have indicated that these events represent simple coincidence.[157] A full review of all reports and studies has absolved the vaccine of most, if not all, of the alleged high incidence of serious or fatal reactions.[157] This and other assessments have resulted in the lessening of public concerns about risks attributable to the vaccine.[158]

Doubts about the continuing need for pertussis vaccine plus anxiety about its safety, widely publicized in the media, resulted in striking diminutions in pertussis vaccine use in the late 1970s in Britain and Japan because of the concerns not only of parents but also of physicians. In both countries, widespread outbreaks of pertussis with its attendant mortality, particularly in unimmunized infants, ensued.[152,159] In Sweden, pertussis immunization was discontinued in 1979 because of doubts about vaccine efficacy, and similarly a recrudescence of the disease occurred.[160] These natural or inadvertent experiments provide strong evidence of the public health merit of continued widespread immunization against pertussis. Any risk of serious disability or death from pertussis vaccine is negligible or nonexistent, and therefore the benefits far outweigh this possibility.

In spite of this, it was clear that it would be advantageous to have an improved pertussis vaccine. First, the whole-cell vaccine undoubtedly contains antigens and other substances that not only are reactive (though not truly dangerous) but also are irrelevant to immunity and contribute to physicians' and parents' concerns about DTP. Second, from the standpoint of children, a less unpleasantly reactive vaccine is desirable and would be more acceptable in both developed and developing countries. Third, booster doses for adolescents and adults are needed to control pertussis and whole-cell pertussis vaccines are poorly tolerated in older children and adults. For these reasons and the fact that a much better understanding of the biological anatomy of *B. pertussis* has evolved steadily, acellular vaccines have been developed and are now used exclusively in most developed nations.

It is clear that these acellular vaccines are at least as immunogenic and far less reactive than whole-cell DTP, including in infants.[39,161,162] A number of randomized, controlled clinical trials of various acellular DTP products (DTaP) were conducted in infants. Efficacy was compared with whole-cell DTP. The results of these studies showed clinical protection comparable to the whole-cell product.[163]In studies in Sweden[84] and Italy[85] supported by the US National Institutes of Health, two acellular pertussis vaccines comprising PT, FHA, and pertactin and a third comprising PT, FHA, pertactin, and fimbriae 2 and 3 were 85% effective against the WHO case definition of pertussis. In other studies, vaccines containing PT alone,[164] PT and FHA,[165,166] and PT, FHA, pertactin, and fimbriae[167]were also effective. Although the methodology of the studies varied, thereby making direct comparison of all of the vaccines impossible, most experts have concluded that acelluar pertussis vaccines containing at least PT, FHA, and pertactin were superior to PT or PT and FHA vaccines and that fimbriae may provide benefit against milder cases of pertussis.[126,163] Long-term follow up of these studies has demonstrated persistence of protection out to six years; surveillance for continued protection is ongoing.[168]

From these studies, it may be concluded that acellular pertussis vaccines appear to be as protective as whole-cell DTP in infancy. The improved safety profile of the

acellular pertussis vaccines has also led to less reports of encephalopathy, hypotonic-hyporesponsive episodes, and febrile seizures.[169,170] Injection-site reactions are initially less common with the use of acellular pertussis vaccines but increase after the fourth and fifth consecutive dose of an acellular product.[171–173] However, injection-site reactions associated with the acellular pertussis vaccine are characterized by painless redness and swelling compared to painful swelling associated with the whole-cell vaccine. Thus, these injection-site reactions appear to be of far less concern to the children and their parents.[174]

In view of the rising incidence of pertussis amongst adolescents and adults and the concern that these individuals serve as the reservoir for infection in young infants, acellular vaccines formulated for adolescents and adults have been developed and are now licensed through much of the world. In North America, acellular pertussis vaccines are recommended at 2, 4, 6, and 18 months of age with a booster prior to school and in early- to mid-adolescence.[175,176] A single dose of an acellular pertussis-containing vaccine is also recommended for all adults;[177] the need for repeat doses in adults awaits data on antibody persistence.

10. Unresolved Problems

Despite the use of effective vaccines in children, in the past decade, reported pertussis incidence has been increasing in many countries with high vaccine coverage such as Canada, Australia, and the United States. This increase, due to waning of vaccine-induced immunity, is occurring mostly in adolescents and adults in whom pertussis is better recognized and probably more frequent. With the implementation of adolescent vaccination programs, there will remain two areas for better control: adults and newborns.

As acellular pertussis vaccines administered to adolescents will not provide a lifelong protection, repeated booster doses will be needed to protect adults. It will be important to determine the interval between booster doses required to maintain protective immunity. The duration of this interval will be critical in assessing the cost and feasibility of programs aimed at preventing pertussis throughout the entire lifetime. Better information is also needed to determine the burden of pertussis illness and the immunogenicity of the acellular pertussis vaccine in the elderly in whom the disease is more severe. In parallel, it will also be important to estimate more accurately the duration of the protection induced by natural (re)infection. These (re)infections, symptomatic or not, are frequent in adults, play a central role in the current epidemiology of pertussis, and may be modified by adolescent vaccination programs.

Development of effective interventions to prevent pertussis in newborns is the other great challenge. Maternal immunization during pregnancy and vaccination of household contacts of the newborns have been proposed but proof of their efficacy is lacking.

Further improvement in diagnostic tests for pertussis is also a research priority in view of the poorer performance of the current tests in adolescents and adults. Standardized, single-serum diagnostic tests and point-of-care testing would greatly facilitate both the diagnosis of disease and the accurate determination of the burden of disease in various subpopulations.

Further research is needed to determine the efficacy of chemoprophylaxis of household contacts to prevent secondary cases. Finally, while antibiotics in cases do reduce shedding and transmission, they do not have a significant impact on symptoms. There is a need to develop a treatment that will stop or alleviate the symptoms of pertussis.

ACKNOWLEDGMENT

We gratefully acknowledge the contribution of the late Dr. Edward A. Mortimer, Jr. who was the former author of this chapter that formed the foundation for the current version. Ted's contribution to pertussis epidemiology can be updated but never replaced.

CHAPTER 28

Plague

David T. Dennis and J. Erin Staples

1. Introduction

Plague is a zoonotic infection of rodents caused by *Yersinia pestis*. Fleas transmit the infection between rodents and incidentally to humans and other susceptible mammalian hosts. Inoculation of the plague bacillus through the skin or mucous membranes produces an acute illness with fever and swollen, painful, regional lymph nodes, the hallmark of *bubonic plague*. Bloodstream invasion may lead to *septicemic plague* or to establishment of infection of other organ systems such as the lung or the meninges. Systemic spread to the lungs may result in *secondary pneumonic plague*, which can then be transmitted by the airborne route via infective respiratory droplets. Airborne transmission is uncommon and typically results at most in one or a few cases of *primary pneumonic plague* among close contacts of the coughing patient; rarely, an outbreak may occur.

Historical epidemics of plague spread rapidly. Attack rates and fatality ratios were high: 50–60% of bubonic patients died; pneumonic and septicemic patients almost invariably experienced a fulminant, fatal course. Prevention measures seemed futile, and epidemics understandably caused panic and upheaval. Even today, despite the availability of curative antibiotics and effective control measures, plague provokes alarm and irrational responses. The increasing concern with bioterrorism and the designation of *Y. pestis* as a Category A select agent have led to renewed concerns about the disease.[1,2]

Dennis • Division of Vector-Borne Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Public Health Service, US Department of Health and Human Services, Fort Collins, Colorado 80521, USA. **J. Erin Staples** • Division of Vector-Borne Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Public Health Service, US Department of Health and Human Services, Fort Collins, Colorado 80521, USA.

2. Historical Background

The earliest description of pandemic plague is that of the Great Plague of Justinian in the 6th century AD, which appeared first in Egypt and extended through the Middle East, North Africa, and parts of Europe. According to some accounts, half the population of the Roman Empire died from this scourge. However, descriptions of clinical illness and measures of mortality in this and other historical epidemics are poorly documented.[3,4]

In the 14th century, pandemic plague recurred. This medieval pandemic is thought to have begun in central Asia, first striking China and Northern India before moving along trade routes to the Crimea and the Levant. From these points, it spread by ship to Italy in 1347, and onward through Europe and to England in 1348. Records indicate fatality rates as high as 40% or more in some concentrated European population centers, and the epithet "The Great Mortality" was applied with good reason;[3–5] "Black Death" was coined later, specifically in relation to epidemics that had great numbers of pneumonic plague.[6] The practice of quarantine, a waiting period before docking of ships arriving from plague-affected areas, was initiated by Italian authorities during this pandemic.

Plague intermittently re-emerged in Europe during each of the four succeeding centuries. The "Great Plague" of London peaked in 1665 when deaths in August and September of that year were reported to be 7,000 per week in a population of 500,000. Plague gradually disappeared from the region in the 18th century, and Europe was apparently free of plague by 1840.[5] Zinsser[7] considered that this disappearance "... presents one of the unsolved mysteries of epidemiology ..." and Pollitzer[8] notes that "... this has been the subject of much debate and few conclusions." Others[5] attribute this freedom from plague to the

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_28,
© Springer Science+Business Media, LLC 2009

displacement of the black rat in European homes by the less-dangerous plague host, the Norway rat.

Epidemic plague reappeared in the last half of the 19th century, apparently originating in Southwestern China, reaching Hong Kong in 1894, and becoming the Third (Modern) Pandemic.[8] From Hong Kong, it spread by cargo vessels to all inhabited continents, newly affecting the Americas. India experienced especially severe epidemics over a 30-year period, resulting in more than 20 million cases and 10 million deaths. In 1894, in Hong Kong, Alexandre Yersin first isolated the causative organism.[9] Studies in India demonstrated that rats were natural reservoirs of infection and also proved the role of fleas in the transmission of the plague bacillus.[5] To combat epidemics of bubonic plague, antisera received extensive study, and various types of vaccines, live attenuated and inactivated whole cell, were made and tested.[10] During World War II, clandestine efforts were made by several combatant nations to weaponize plague, and crude experimental devices were used against some Chinese civilian populations.[1] Curative antibiotic therapy was first demonstrated in the late 1940s and early 1950s using streptomycin, chloramphenicol, and tetracycline.[11,12]

Advances in community sanitation and hygiene have done much to limit contacts of humans with rodents and their fleas; although plague is a widespread zoonosis, disease in humans has in the past 50 years occurred mostly as sporadic cases and clusters, punctuated by occasional limited outbreaks. A notable exception is the prolonged epidemic plague activity that occurred in war-disrupted Vietnam during 1962–1975,[13–16] and a brief resurgence of urban and rural disease in Madagascar in the 1990s.[17]

3. Methodology

3.1. Sources of Morbidity and Mortality Data

Until 2005, International agreements required immediate notification to the World Health Organization (WHO) of the first case of plague in any area previously free of the disease, as well as regular reporting of all confirmed cases. With the adoption and implementation of the updated International Health Regulations (2005), plague is no longer required to be reported by participating states and the WHO will no longer be publishing plague surveillance data.[18] Under the new regulations, however, if plague is consider to "constitute a public health emergency of international concern", it should be reported to the WHO. In addition to the international regulations, individual countries have various regulations governing reporting in their jurisdictions. Global and regional plague surveillance information was published in the WHO *Weekly Epidemiological Record* and in the *Weekly Epidemiological Report* of the Pan American Health Organization up until 2005. For the United States, the Centers for Disease Control and Prevention (CDC) continues to publish annual plague surveillance information in the *Morbidity and Mortality Weekly Report*. Previous WHO-published worldwide figures are thought to be approximately correct, although significant lapses occur; e.g., plague deaths are not routinely reported by some countries, and information on contained outbreaks is sometimes withheld. There is a tendency for underreporting at the onset of an epidemic and overreporting during its course. Sporadic cases are easily missed, especially those that are treated with antibiotics in early illness and fail to develop a typical clinical picture.

Variations in reporting criteria also contribute to unreliable statistics. In the United States, only laboratory-confirmed cases are reported, whereas in some countries, once there is reason to believe an outbreak is in progress, suspect cases are reported with or without laboratory evidence of infection. Further, the vast majority of cases of human plague occur in rural areas of the developing world where surveillance is poor and access to reliable laboratory testing is limited. Information on reported epidemics of plague in India in 1994 was confused by the use of various and nonspecific case definitions and unreliable laboratory confirmation of cases. Consequently, there was overreporting of cases and conflicting statistics, and important epidemiological and etiologic features of this episode are unclear.[19]

3.2. Surveys

Routine microbiological methods are available for the isolation of *Y. pestis* and for serodiagnosis in humans, rodents, and carnivores. Environmental surveys are based on evaluating ecosystems of involved rodent populations, collecting and identifying rodent and rodent flea species and determining *Y. pestis* infection in them, and collecting and testing of carnivore serum for evidence of recent infection.[20–23] These surveys may be helpful in assessing the health risk, in prompting control and prevention measures (e.g., alerting the public, taking measures to control rodent fleas and rodents, and restricting public access to infected areas), and in evaluating the impact of such interventions.

4. Biological Characteristics of the Organism

4.1. Etiologic Agent, *Yersinia pestis*

Yersinia pestis is a gram-negative, nonmotile, nonsporulating, coccobacillus in the family Enterobacteriaceae.

Molecular genetic studies show that it evolved directly from *Yersinia pseudotuberculosis* less than 20,000 years ago.[24,25] It is microaerophilic, oxidase- and urease-negative, and biochemically unreactive. *Y. pestis* is nonfastidious and grows slowly but well on simple bacteriologic media.[26] It grows best at 28°C and a pH of 7.4. When incubated on agar plates, it produces pinpoint colonies at 24 h and 1–2 mm diameter colonies at 48 h. Colonies are gray-white with irregular surfaces that have a hammered metal appearance when viewed under magnification. In broth, the organism grows in clumps that cling to the sides of the culture tube and the broth itself remains clear. *Y. pestis* readily infects laboratory rodents, which are used in specialized laboratories for virulence testing and for isolating the organism from contaminated materials.

4.2. Virulence Factors

Virulence factors are important in the organism's ability to replicate in fleas and mammals.[26,27] Most genes encoding these virulence factors reside on three plasmids, *Pst* (9.5 kb), *Lcr* (~70 kb), and *pFra* (~110 kb), but some are associated with chromosomes. The *Pst* plasmid encodes a plasminogen activator (Pla) and a bacteriocin (pesticin). The temperature-dependent plasminogen activator, a single-bacterial surface protease, is important for survival of *Y. pestis* in fleas. This protease facilitates the formation of a bolus of blood and aggregated bacteria in the flea midgut, which blocks the flea's proventriculus and leads to regurgitation of infective material when the "blocked" flea attempts to feed.

At least six determinants of *Y. pestis* virulence in guinea pigs and in mice have been identified, and it is thought that most of these are important in human infection. Fraction 1 antigen (F1) is contained in the diffusible envelope of the organism and is associated with protection against neutrophilic phagocytosis. Expression of this antigen is temperature dependent; maximum F1 production occurs between 32 and 37°C and does not occur below 28°C. Because the ambient temperature of fleas is typically less than 28°C, *Y. pestis* in the flea gut lacks F1, and organisms inoculated into mammalian hosts by fleas are initially vulnerable to neutrophilic phagocytosis. Those that survive develop in vivo resistance to neutrophilic phagocytosis.[26,28]

Yops, V, and W virulence proteins are known as low-calcium response proteins and are thought to inhibit phagocytosis and to mediate the inflammatory and cell-mediated immune response to infection.[26,27] Pesticin (Pst) and plasminogen activator protease (Psa) are associated with the production of a fibrinolytic factor and a coagulase. The interplay between Pst and chromosomal iron regulatory genes influences hemin storage and iron transport. Strains that are able to utilize exogenous hemin bind congo red in culture and produce pigment. Murine toxin (Ymt) is specific and highly lethal to mice and less so to rats, but it is not known to be toxic in humans. In the flea midgut, Ymt (recently recognized to be phospholipidase D) plays a critical role in protecting *Y. pestis* from a cytotoxic digestion product of blood plasma. The emergence of Ymt did, by adapting the bacillus to fleas, radically separate the natural history of the plague bacillus from that of the enteropathogenic *Yersinia* spp.[28]

In routine culture of *Y. pestis*, some colonies may be found that lack certain virulence factors. Pigment-negative colonies are the most common findings.[29] Laboratory procedures for isolating *Y. pestis* by inoculating laboratory animals may select against isolates that lack certain virulence factors. Testing for these factors should be done on fresh isolates, because laboratory manipulation, particularly prolonged incubation at 37°C, may result in loss of virulence.

4.3. Geographic Biotypes

Biotypes of *Y. pestis* based on nitrate reduction and ability to ferment glycerol were described by Devignat.[30] These biotypes are not related to virulence, but were thought to be of epidemiological interest as markers of evolving lineages. The Orientalis biotype spread from East Asia to many areas of the globe in the Third Pandemic, including the Western Hemisphere. It is characterized by its ability to reduce nitrate and an inability to ferment glycerol. Variety Mediaevalis, found only around the Caspian Sea, does not reduce nitrate but ferments glycerol. Variety Antigua, present in Southeastern Russia, Central Asia, and parts of Africa, both reduces nitrate and ferments glycerol. Although ribotyping studies of various plague strains generally support the biotyping distinctions,[31] results of recent molecular genetic studies contradict neat historical compartmentalizations.[32,33]

4.4. Flea Vectors

Fleas are the only known arthropod vectors of plague. They typically leave a dead host as its body temperature drops and seek a warm-blooded replacement, enhancing spread of infection. Many flea species are strongly host specific; others, such as *Xenopsylla cheopis* (the oriental rat flea), which is the principal vector of urban epidemic plague, are promiscuous in their host selection. Other important vectors of plague to humans are *X. astia, X. braziliensis, X. vexabilis, Nosopsyllus fasciatus*, and in the United States, the wild rodent flea, *Oropsylla montana*.[8,20]

When *X. cheopis* ingests blood containing *Y. pestis*, bacilli multiply and form an alimentary canal blockage at the level of the proventriculus. The observation that epidemics of bubonic plague waned when ambient temperatures exceeded 28°C led to studies demonstrating that *X. cheopis* enzymatically lyse their intestinal blockage at temperatures above 28°C. Cleared fleas could feed without regurgitation and were no longer efficient vectors.[34] Newer studies using both *X. cheopis* and *O. Montana* fleas have demonstrated, however, that the fleas can transmit *Y. pestis* during the early phase of infection without an intestinal blockage and thus challenge the need for intestinal blockage for effective transmission and spreading of plague.[35,36] The vector competency of fleas is evaluated by comparing them to the prototypic, highly efficient vector, *X. cheopis*.[21,37]

4.5. Rodent Reservoirs

Of the more than 200 species of rodents found to be naturally infected by *Y. pestis*, many are unimportant in maintaining zoonotic cycles of infection and only a few pose significant risks to humans. *Rattus rattus*, the domestic black rat (house rat, roof rat), is the most dangerous. It has a cosmopolitan distribution, lives in close association with humans (nesting in attics, wall spaces, etc.), is a vigorous breeder, is a host favorable to *X. cheopis*, and typically develops fatal septicemic plague. In epizootics, rats serve as efficient amplifying hosts of *Y. pestis*. "Rat-fall" refers to the observable die-off of affected rat populations and is a forewarning of epidemic plague. However, rat populations that have experienced extended periods of plague activity may become relatively resistant to infection, and rat-falls may cease even though transmission of *Y. pestis* continues. *R. norvegicus* (Norway rat, sewer rat) is an aggressive territorial competitor of the black rat. It is a burrowing rodent that lives peridomestically and frequents cellars, drains, crawl spaces, and foundation areas of buildings. In rural areas, the Norway rat may be an efficient vectorial link between the wild rodents and the more domestic black rat. When wild rodent plague is contiguous with rat and oriental rat flea populations, the potential for epidemic plague is great.[8]

Important noncommensal sources of plague throughout the world include marmots, gerbils, and ground squirrels in Northern Asia; gerbils and ground squirrels (susliks, sisels) in Central Asia and the Near East; gerbils and bandicoot rats in India; the Polynesian rat (*Rattus exulans*) and shrews in Vietnam; *R. exulans* in Indonesia; gerbils, grass rats, and some species of multimammate mice in Africa; ground squirrels (*Spermophilus* spp.), prairie dogs (*Cynomys* spp.), and chipmunks (*Tamias* spp.) in the United States; and guinea pigs (*Cavia* spp), rice rats (*Oryzomys* spp.), and cotton rats (*Sigmodon* spp.) in South America.[8,20,38]

5. Epidemiology

5.1. Occurrence of Human Plague

During 1989–2003, a total of 38,359 human cases of plague was reported to the WHO from 25 countries (mean of 2,557 cases per year) (Table 1).[39] The reported case fatality ratio was 7%. More than 80% (31,273) of the total number of cases were reported from African countries, about 14% (5,449) from Asia, and the rest from the Americas (1,637). Countries reporting the highest number of cases were Tanzania, Zaire, and Madagascar in the African region; Vietnam and Myanmar in Asia; and Peru in the Americas.

Table 1 Reported Cases of Plague in Humans by Country, 1989–2003

Continent	Country	No. of cases	No. of deaths
Africa	Algeria	11	1
	Botswana	173	12
	Kenya	44	8
	Madagascar	13,148	1132
	Malawi	907	16
	Mozambique	2387	28
	Namibia	2012	80
	Tanzania	5249	335
	Uganda	821	130
	Zaire	4935	616
	Zambia	1169	29
	Zimbabwe	417	34
	Total	31,273	2421
America	Bolivia	37	6
	Brazil	105	0
	Ecuador	14	14
	Peru	1380	60
	United States	101	10
	Total	1637	90
Asia	China	519	52
	India	892	58
	Indonesia	6	0
	Kazakhstan	24	7
	Lao People's Democratic Republic	10	0
	Mongolia	115	36
	Myanmar	761	6
	Vietnam	3122	175
	Total	5449	334
World total		38,359	2845

Recent outbreak activity has been reported from Democratic Republic of Congo, India, Algeria, Zaire, Madagascar, Mozambique, Zambia, Malawi, Indonesia, and Educador. India, in 1994, reported a total of 876 bubonic and pneumonic plague cases with 54 deaths, but the number of confirmed cases was much less.[19,40]

In the United States, 129 confirmed cases of plague in humans were reported during 1989–2006 (average 7 cases per year). Of these cases, 78% occurred in the Southwestern states of New Mexico, Arizona, and Colorado; 9% were reported from California; nine other western states reported small numbers of cases, and one case was imported (CDC, unpublished data). Most likely modes of transmission were determined for 71 of these cases and included flea bite ($n = 27$; 38%) and direct contact with infected animals ($n = 44$; 62%). Of the 44 persons thought to be infected by direct contact with animals, just under half [17] reported exposure to an infected domestic cat. The overall case-fatality ratio was 10%. In the United States, most cases of plague occur in the summer months when rodent and rodent flea activities are greatest. The majority of cases, especially those in the southwestern states, are acquired in the environs of the patient's residential property [41,42]; less often, plague in the United States is acquired by persons working or recreating in natural areas remote from their places of residence.

5.2. Contagiousness

Uncomplicated bubonic plague is not contagious and patients do not place their family, other social contacts, or attendants at risk. Household members, however, may be at risk of exposure to the same zoonotic source as the index case. Most plague exposures occur in rural foci, where cases are more likely to be sporadic than epidemic. When a bubonic or septicemic plague patient develops secondary plague pneumonia, person-to-person transmission becomes possible but rarely occurs; no person-to-person plague cases have occurred in the United States since 1924, even though 67 pneumonic plague cases have been recorded since then, including six with primary pneumonic plague acquired from domestic pets (five cats, one dog) with respiratory plague (CDC, unpublished data). The presence of *Y. pestis* in the throats of presumably healthy persons has been described,[43] but there are no data to suggest that such "carriers" play any role in the transmission of the infection. Any draining buboes or other cutaneous lesions of plague patients should be considered infectious, but experience indicates that risk of infection by direct contact with exudates is minimal.

The plague bacillus does not survive well in the environment. Temperatures above 40°C and desiccation are rapidly lethal to the organism, and airborne organisms have a short-survival period. Pneumonic plague is transmitted by respiratory droplet, and *Y. pestis* does not become truly aerosolized in an infectious state. Respiratory droplet spread occurs only when there is close, face-to-face contact (<2 m).

5.3. Geographic Distribution

Countries reporting human plague are noted in Table 1.[39] The probable distribution of active enzootic plague foci throughout the world is shown in Figure 1.

5.4. Environmental Factors

Ambient temperature and humidity regulate rodent host populations as well as the survival and continued infectiousness of their fleas. Bubonic plague epidemics have occurred most notably in temperature ranges of 10–26°C associated with a high-relative humidity.[8,34,38] These conditions are most favorable for plague epizootics in rats. On the other hand, enzootic wild rodent plague foci are most often associated with semi-arid regions.[20,21,38] In tropical environments, outbreaks tend to occur at the end of the dry season, when the temperature falls and humidity rises. In India the rainy season differs between the northern and the southcentral plague foci, so that no generalization as to time of year for greatest plague activity can be given for the country as a whole.[8] In Vietnam, human plague incidence was found to be sensitive to slight variations in temperature, relative humidity, and vapor pressure.[34,37,44]

Pneumonic plague epidemics have occurred in winter in circumstances of high-relative humidity and overcrowding; this was most dramatically demonstrated in Manchuria during two major epidemics in the early 20th century, when tens of thousands of persons died in epidemics of pneumonic plague.[6] The California urban plague outbreaks in 1919 and 1924, and the recent descriptions of pneumonic plague in highlands of Madagascar, are examples of limited transmission of pneumonic plague in moderate climates.[17,45]

The principal environmental determinants of risk to humans of rat-borne plague are the underlying sanitation and the conditions of homes and places of work that support rat populations with food and harborage. Populations of wild burrowing rodents fluctuate with the availability of edible vegetation.

5.5. Demographic Factors

Demographic differences in rates of disease can be explained by exposures associated with place of residence, cultural and socioeconomic factors, occupational and recreational activities, and other behavioral factors.[46] Poverty,

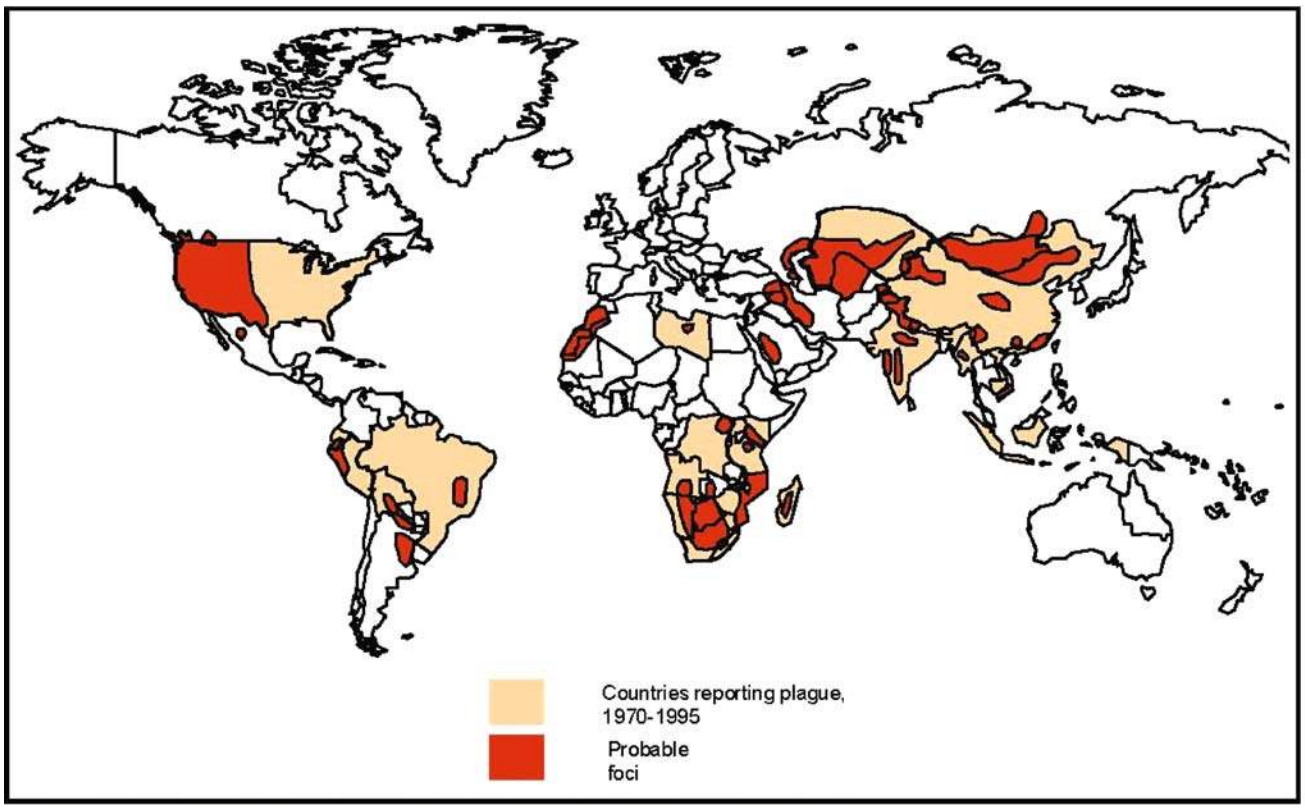

Figure 1. Distribution of natural foci of plague. Compiled from WHO, CDC, and other sources.

crowding, and poor sanitation are risk factors for rat-associated plague.

5.6. Occupation and Recreation

Certain occupational and recreational activities are associated with an increased risk of exposure to infected fleas. Persons who work or recreate in areas where there are large populations of burrowing rodents such as prairie dogs and ground squirrels, including hunters, trappers, naturalists, pet owners, and campers, may be at an elevated risk of infection.[47,48] This is important in explaining the relatively large numbers of cases that occur among Native Americans in the southwestern United States.[48,49]

In Mongolia, and in some high-elevation areas of Central Asia, marmot hunting and skinning is an important risk factor for plague.

5.7. Occurrence in Different Settings

When family or household clusters of bubonic cases occur, the dates of disease onset usually occur within days of each other. Where multiple cases have occurred within a larger community from a single-epizootic source, dates of onset are usually separated by weeks and involve multiple and geographically separated households. Pneumonic plague patients pose a threat to immediate contacts including family members, friends, and medical personnel. Travel during the incubation period of plague, including long-distance air travel, has been described in the United States as peripatetic plague[50,51] and occurred most recently in 2002, when two persons became ill while traveling in New York City.[52] Molecular subtyping showed that the patient isolates were indistinguishable from rodent isolates obtained near their home in New Mexico. Some traveling patients developed secondary pneumonic plague and were contagious for variable periods before being isolated and treated. Fortunately, the risk of pneumonic transmission is high only when there is a productive cough and close face-to-face exposure.[17,53,54] Disruptions of war have often been associated with plague epidemics. Invading or retreating troops have introduced the disease by transporting infected rodent hosts or their fleas in shipments of grain, other food stuffs, and material.[8,38]

Movement and crowding of refugees provide the opportunity for pre-existing plague to become epidemic.[55]

5.8. Socioeconomic Factors

In rat-borne disease, persons with low incomes are generally the most affected. Factors include poor-quality housing that allows ready access to and harborage for rats; housing located near docks, warehouses, or granaries; crowding; and poor environmental hygiene and sanitation. In the United States, cases arise primarily from wild rodent epizootic sources and all socioeconomic groups are affected. The affluent build expensive homes in rural areas with the intention of retaining as much of the natural habitat as possible, sometimes in the midst of an enzootic plague focus. Decorative rock walls form ideal "rocky outcroppings," the principal habitat of the rock squirrel (*Spermophilus variegatus*), an important plague host in the Rocky Mountain region. On the other hand, some persons who live in close proximity to enzootic plague foci encourage rodent encroachment (especially by wood, or pack, rats) by providing peridomestic food and harborage in the form of garbage, junk piles, old cars, tires, and wood piles.[47] Prairie dogs may invade overgrazed pastures surrounding or adjacent to human dwellings, which has been especially problematic on Native American lands in the Southwestern United States and increasingly at the interface of the plains and Rocky Mountain foothills in Colorado.

6. Mechanisms and Routes of Transmission

The sources of *Y. pestis* infection of humans are bites by infected fleas; direct contact with the blood or tissues of infected animals captured, hunted, or found dead; persons or pets with plague pneumonia; ingestion of raw or undercooked meat from an infected animal; and rarely the mishandling of plague cultures in the laboratory. Infection can take place through the skin, the respiratory tract, the conjunctiva, the oropharyngeal mucosa, and the digestive tract. Infection by direct conjunctival or mucous membrane exposure is of concern to persons caring for patients with plague pneumonia, laboratorians, and persons who dissect or butcher infected animals.

Entry of the plague bacillus through the respiratory tract may result in two clinical patterns, depending on the size of aerosolized particles introduced, either pharyngeal or pneumonic plague. Experiments in guinea pigs showed that bacilli contained in large-particle sprays were most likely to lodge in the oropharynx resulting in pharyngeal plague and secondary septicemic plague, while smaller particles initiated bronchopneumonia; in experiments with larger animals such as monkeys, inhalation either of single-organism clouds or infectious particles 12 μm in diameter produced lobar pneumonia.[56] Transmission of pneumonic plague among humans is thought to occur through respiratory droplets as transmission by droplet nuclei has not been demonstrated.[53,54]

Domestic cats develop bubonic plague with submandibular and/or cervical lymphadenopathy and associated ulceration, and abscesses, or they can develop pharyngeal or pneumonic plague as a result of ingesting infected rodents.[57,58] Humans can acquire various forms of plague from cats by inhaling infective respiratory particles, by skin or mucous membrane contact with infectious exudates or secretions, or by being bitten or scratched. Ingestion of undercooked infected wild rodents (especially marmots and prairie dogs) and of infected camel and goat meat has resulted both in sporadic cases and limited outbreaks of human plague, which manifest as plague pharyngitis, septicemia, and meningitis.[59]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Following the bite of an infected flea or other cutaneous introduction, local *Y. pestis* proliferation ensues but is often not apparent; a small papule or vesicle containing a clear or hemorrhagic fluid (a phlyctenule) sometimes occurs at the site of inoculation and rarely a crater-like ulcer mimicking that of tularemia develops at the site.

From the site of inoculation, organisms travel by way of the lymphatics to regional nodes. The disease may be contained at this level as in simple bubonic plague, or localized infection may be followed by bloodstream invasion with intermittent bacteremia or septicemia. Septicemic plague may occasionally develop with no apparent local lymphatic involvement (primary septicemic plague). Some of these patients are thought to have occult involvement of intra- or retro-peritoneal nodes. Bloodstream dissemination may lead to secondary plague pneumonia, plague meningitis, multiple lymphadenopathy, and involvement of other organs, such as the liver, spleen, and rarely the eye.

The principal direct pathogenic effect of invasion is acute local inflammation and hemorrhagic necrosis of affected tissue. This will trigger the release of cytokines and other inflammatory mediators that in turn can activate the complement cascade. Systemically, the patient responds with fever and endotoxemia. A septic shock syndrome can

develop leading to refractory shock, organ failure, acute respiratory distress syndrome, and disseminated hemorrhagic manifestations, including petechiae, ecchymoses, and frank bleeding.[60]

7.2. Incubation Period

The incubation period of bubonic plague is generally 2–6 days,[8] and is typically 3–5 days for pneumonic plague, but shorter and longer intervals have been reported.[13,14,61]

7.3. Immunity

Susceptibility of rodents to *Y. pestis* varies from one species to another. Species that are moderately resistant and have a low mortality are important in maintaining plague in a focus and are termed *enzootic* or *maintenance hosts*. They usually coexist with susceptible rodent species that experience a high mortality from infection (epizootic, amplifying hosts). In the United States, inherent species susceptibilities range from highly resistant (kangaroo rats) to highly susceptible (prairie dogs).[22] Studies of the natural resistance in rats from a plague-free area showed that some survivors of a small challenge inoculum that developed antibody responses survived a rechallenge with a similar or larger inoculum, while most of those that did not develop antibodies died.[62]

Most humans develop antibody responses to infection with *Y. pestis*.[63] In a recent CDC review (unpublished) of 89 confirmed plague cases in the United States, only 4 (4.5%) cases did not develop antibodies to F1 of *Y. pestis*. Asymptomatic infection in humans appears to be rare, but some evidence for this was found in Madagascar by detecting plague antibodies in persons from whom no history of illness could be elicited.[64] On the other hand, serosurveys of 716 community and household contacts of cases living in plague-enzootic areas of the United States and 167 residents of two villages in Indonesia during a rat-borne plague epidemic there revealed only four seropositive samples. One, with a titer of 1:128, was a missed bubonic plague case who had onset of illness 3 weeks prior to the survey; one was a Vietnam veteran with a titer of 1:32 who had been previously immunized; two were residents of an Indonesian village with titers of 1:16 and 1:32, respectively, and who had no history of recent illness or of vaccination.[65] This suggests that subclinical infection was rare to nonexistent in those cases.

Persons previously immunized with formalin-inactivated plague vaccine USP may develop titers against *Y. pestis* that persist for decades. Prior plague vaccination may confound results of serological testing if a history of vaccination is not considered.

The degree of protection provided by plague antibodies in humans is not fully known. Experience in Vietnam suggests that natural infection may not produce complete immunity.[64] And, although the inactivated plague vaccine available in the United States in the past was shown to be an efficient immunogen, its protective efficacy was never tested in controlled clinical trials. Comparisons of immunologic responses to vaccination by humans and animals and field experiences with vaccinated military personnel provide indirect evidence that the inactivated vaccine was protective against bubonic plague in humans.[66] Recently developed recombinant F1 and V antigen vaccines currently undergoing clinical trials are reported to be protective in mice and highly immunogenic in humans.[67]

8. Patterns of Host Response

The clinical response of humans to *Y. pestis* infection is diverse, ranging from mild, ambulatory bubonic plague to rapidly progressing septicemia with bleeding, shock, multiple organ failure, and death.[68–72]

8.1. Clinical Features

The clinical forms of plague that arise from primary exposure include bubonic, septicemic, pneumonic, pharyngeal, and possibly gastrointestinal plague; secondary manifestations that result from lymphatic or hematogeneous spread to other organ systems include multiple lymphadenitis (sometimes involving intra-abdominal and thoracic lymph nodes), plague pneumonitis, meningitis, abscess formation in the liver or spleen, and endophthalmitis.[16,68,72]

Two to six days after exposure, bubonic plague patients typically experience sudden onset of illness characterized by severe malaise, headache, shaking chills, fever greater than 38°C, and pain in the area of affected regional lymph nodes, which may not be palpably enlarged at this stage. Progression of symptoms is usually rapid with the affected nodes (buboes) often becoming excruciatingly tender and painful as they enlarge. Definition of small to moderately enlarged buboes may be obscured by extensive perinodal edema, erythema, and induration. During the course of the first 3–5 days of illness, the patient may, if not treated, develop gram-negative sepsis, endotoxin-induced systemic inflammatory response syndrome, consumptive coagulopathy, subcutaneous and widely disseminated hemorrhages, septic shock, multiple organ failure, adult respiratory distress syndrome (ARDS), mental confusion, and death.[68–72] Buboes may or may not suppurate.

In primary pneumonic plague, usually within 3–5 days after exposure, the patient experiences a chill followed by fever, splinting of the chest, and cough with production of a thin, serosanguinous sputum. Segmental pulmonary consolidation may occur, manifested by dullness to percussion and decreased breath sounds. A more diffuse interstitial pneumonitis may develop and progress rapidly. Not infrequently, auscultatory findings are surprisingly minimal compared to what is seen by roentgenography. Lobar pneumonia, abscess formation, and cavitation are unusual complications of pulmonary infection. If efficacious antibiotics and aggressive supportive care is not provided within 18 h or so of onset, primary pneumonic plague almost always follows a fulminating course and death within 2–3 days.

Pulmonary infection is a serious public health concern, since respiratory plague is transmissible from person to person. Secondary plague pneumonia occurs more frequently than primary plague pneumonia and is thought overall to be less contagious than the primary form. At time of contagiousness, the secondary pneumonia patient usually has been severely ill for 2 or more days with sepsis, is less capable of mustering a vigorous cough, and most often produces sputum that tends to be thick, mucopurulent, and tenacious. In comparison, the primary pneumonic plague patient is more likely to produce a thin, watery, dispersable serosanguinous or bloody sputum early in the disease and to cough with more vigor.

8.2. Differential Diagnosis

When bubonic plague occurs in epidemic form, it is readily diagnosed. Conversely, the diagnosis of an isolated case is often missed, particularly in the early stage of illness. Plague should be considered in any patient presenting with acute onset of fever, lymphadenitis, and a history of residence or travel in a known plague area. Other causes of lymphadenopathy, however, must be investigated: gram-positive bacteria are probably the most common cause, and a Gram's stain of a bubo aspirate should quickly differentiate between gram-positive cocci and gram-negative bacilli. The list of differential causes of lymphadenopathy is long, and plague cases have been misdiagnosed as cat scratch fever, lymphoma, appendicitis, and incarcerated inguinal hernia, to name a few. Bubonic plague and tularemia may be confused in areas where both diseases occur.[73] A skin lesion at the site of inoculation may be seen in both diseases. From a clinical standpoint this may not be a critical distinction, since both respond to the same antibiotic therapy; however, for public health and epidemiological reasons, a missed case of plague is potentially serious. The marked tenderness and pain of affected lymph nodes of bubonic plague patients present a sharp contrast to the relatively milder discomfort that occurs with most other infectious causes of lymphadenitis.

Pneumonic plague may be confused with severe acute respiratory illness, including ARDS, from other causes. In the United States, pneumonic plague has been confused with hantavirus pulmonary syndrome and vice-versa. A history of recent exposure to a person with severe fatal pneumonia, or to a pet cat with an acute febrile illness, cervical or submandibular lymphadenopathy or abscess, or bloody respiratory discharge[59,74,75] should prompt the clinician to consider plague. It is critically important to obtain a careful and thorough history of animal exposures from every suspect plague patient.

When plague is considered, an examination of bubo aspirate or sputum by Gram's stain and by a polychrome stain should guide the clinician in choosing an appropriate antibiotic. When plague is suspected and other causes of illness cannot be implicated, plague therapy should be started pending the outcome of definitive testing. In patients with suspected bubonic plague who do not yet have a microbiologic diagnosis, it may be prudent to initially include therapy for gram-positive causes of lymphadenopathy; gram-positive bacteria grow rapidly on culture so that a microbiological diagnosis can usually be made within 12–24 h.

8.3. Laboratory Diagnosis

8.3.1. Clinical Specimen Collection and Staining. When plague is suspected, laboratory diagnostic specimens should be collected immediately, chest radiographs obtained, and the patient begun on appropriate antibiotic therapy pending microbiological confirmation. Specimens routinely collected include blood on all patients, lymph node aspirates from those with suspected buboes, sputum samples or tracheal washes from those with suspected respiratory plague, and cerebrospinal fluid from patients with suspected meningitis.

Blood is aseptically collected for culture, for preparation of blood smears on glass slides, and for leucocyte counts. For bubo aspiration, a small, sterile syringe containing a few milliliters of sterile saline is inserted into the central part of the suspect lymph node and an attempt is made to aspirate fluid. If this is not successful, the saline is injected and aspirated. A portion of the aspirate is used to make films on two or more glass slides for routine staining, and at least two slides for direct fluorescent antibody (FA) testing. Slides for staining are prepared by placing drops of the aspirate on glass slides, which are then air-dried and lightly heat-fixed. For routine staining, one slide should be stained by Giemsa or Wayson's method and one by a Gram's stain. To identify *Y. pestis*, specimens of blood, sputum, tracheal washes,

and cerebrospinal fluid should be similarly stained. Under light microscopy, *Y. pestis* is a plump gram-negative bacillus that, with polychrome stains, typically shows a bipolar, closed safety-pin configuration. Fluorescence-stained organisms are identified using darkfield microscopy.[76]

8.3.2. Cultural Isolation of *Y. pestis*. Cultural isolation of *Y. pestis* is important for early confirmation of infection. If the patient's condition allows, at least three blood cultures should be taken over a 45-min period immediately after the diagnosis of plague is suspected and before antibiotic treatment is begun. Blood and other materials, such as bubo aspirates and sputum, should be inoculated onto media such as sheep blood agar, brain–heart infusion (BHI) broth, or MacConkey or deoxycholate agar; when immediate culture is not possible, specimens may be placed in Cary–Blair transport medium. Confirmation of isolates as *Y. pestis* is made by specific bacteriophage lysis.[76]

8.3.3. Serological Diagnostic Methods. The standard serodiagnostic method is the passive hemagglutination (PHA) test utilizing *Y. pestis* F1 antigen. The specificity of a positive antibody–antigen reaction should be validated by hemagglutination inhibition (HI) testing. Acute and convalescent serum specimens should be taken. Serum samples taken 3–4 weeks after onset of symptoms will confirm more than 95% of cases. PHA antibodies tend to remain at high titer ($\geq$64) for months and may persist at low titer for years or for life. An enzyme-linked immunosorbent assay to detect the F1 antigen in serum or blood clot is quite sensitive; however, this procedure does not recognize all blood-culture-positive patients.[77] A complement-fixation test with F1 antigen is comparatively insensitive, especially in early infection. Latex particles coated with F1 antigen have been used successfully in direct and passive agglutination tests, although problems in sensitivity and specificity have been reported.[76]

8.3.4. Rapid Detection Tests. Antigen capture ELISA procedures, polymerase chain reaction assays, and handheld immunochromatographic detection tests for rapid early detection of the F1 antigen have been developed and are being evaluated. The handheld devices permit diagnostic testing of clinical materials at the bedside, even under primitive conditions.[78]

8.3.5. Reference Diagnostic Testing. Whenever the diagnosis of plague is considered in the United States, materials should be sent to clinical laboratories experienced in testing for plague. In addition, the material should be sent to the State Health Department and the CDC, Fort Collins, Colorado 80521, for microbiological confirmation. The Local and State Health Department should be contacted by telephone for reporting of a suspected case, for assistance in diagnostic testing (including the confirmation of an isolate as *Y. pestis*), and for other consultations. The CDC can also be contacted for additional information at 970-221-6400.

8.3.6. Diagnostic Categories. Based on clinical and laboratory findings, cases of plague can be categorized as suspect, presumptive, or confirmed. A *suspect case* is one in which the patient has disease manifestations suggestive of plague as well as consistent epidemiological features. A *presumptive case* is one in which the patient has compatible clinical manifestations and supportive laboratory findings, including gram-negative, bipolar bacilli seen in stained smears of a bubo, blood or sputum; a single seropositive test result for *Y. pestis* infection; PCR detection of *Y. pestis* in bubo, aspirate, or sputum; or F1 antigen detection in bubo, aspirate, blood, or sputum. A *confirmed case* is one in which there is a fourfold or greater change in *Y. pestis* antibody titer between acute- and convalescent-phase serum samples, or in which a bacterial culture of suspected *Y. pestis* is lysed by the uniquely specific bacteriophage used for this purpose. In endemic areas when no other confirmatory test can be performed then a case having a positive rapid diagnostic test using immunochromatography to detect F1 antigen is also considered a confirmed case.[79]

9. Control and Prevention

9.1. General Concepts

The major objective of control is reduction of bites by infective fleas. Education of the general public and health professionals in areas where plague occurs is the first line of defense in plague prevention. Risk factors in those areas must be publicized, especially at the outset of known plague seasons. Physicians, veterinarians, and the public must be alerted to the possibility of plague and know its signs and symptoms. Persons in endemic areas need to know the potential danger from rodent die-offs and should report changes in rodent activity to public authorities. They should also be educated on the need to control fleas on pet dogs and cats; to properly store grains and other foodstuffs that may attract rodents to home, work, or play areas; to rodent-proof homes; and to take appropriate action when there is severe illness, death, or disappearance of a pet cat. Hikers, campers, and others who take part in outdoor recreational activities in areas where plague occurs should (1) avoid handling of sick or dead animals, (2) avoid rodent nests and burrows, (3) use insect repellents containing *N*,*N*-diethyl-m-toluamide (DEET) on skin and repellents or appropriate insecticidal sprays on clothing, and (4) treat accompanying pets with insecticides. Hunters should use gloves when handling dead animals.

During epidemics of bubonic plague, flea control must precede or effectively coincide with rodenticiding. Death of rodent hosts without prior flea control will deprive fleas of their normal hosts, forcing them to seek alternate sources of blood meals, including humans, and greatly increasing the risk of human exposure. Appropriate insecticides should be applied to rodent burrows, nests, rat runs, and other sites where rodents are active. This should be done under the supervision of persons qualified in pest control. Tests should be set up to determine whether the target fleas are susceptible to the insecticides considered for use and to evaluate the effectiveness of flea control efforts.[20,21] After reduction of the flea population, trapping or poisoning of rodents may be appropriate in certain situations. Killing of commensal rodents will provide no benefit unless rodent-proofing of houses and elimination of food and harborage are also undertaken. Rodents will quickly move into the vacated spaces and may aggravate an epidemic situation, since in-migrating rodents are apt to be young and more susceptible to *Y. pestis* than the removed population. During rat-borne epidemics, bubonic plague patients, their clothing, and other effects may still be carrying infected fleas, and decontamination measures may be needed.

Plague is potentially a quarantinable disease covered under international regulations.[80] Following reports of outbreaks of plague in India in 1994, international and national health authorities became involved for the first time in many decades in reviewing, interpreting, and implementing regulations concerning the threat of international spread of plague.[39,81,82] Travel and trade with India was severely disrupted, and the outbreaks were estimated to have cost India more than a billion dollars lost in tourism, commerce, and investment values, disruption of services, and prevention and control efforts. This experience will hopefully lead to improved understanding by public health authorities of the true risks for international spread of plague and the use of more appropriate control measures in future similar occurrences.

Pneumonic plague patients may incubate very large numbers of organisms, but appropriate therapy almost always results in a marked decrease in contagiousness in a matter of hours.

9.2. Antibiotic Treatment

Early treatment of cases with effective antibiotics is important in preventing complications and death, and a principal measure to prevent respiratory spread of infection. Standard antibiotics used in treating plague are doxycycline, streptomycin, and chloramphenicol.[83,84] Increasing numbers of plague patients in the United States are being treated with gentamicin, and evidence is accumulating that this is a safe and efficacious antibiotic for this disease.[85,86] Ciprofloxacin cures plague in laboratory animal experiments and has been recommended as an alternative for both treatment and prophylaxis when large numbers of persons are involved in a bioterrorism exposure.[1,2] A single isolate of *Y. pestis* from a bubonic plague patient in Madagascar was found to be resistant to multiple antibiotics usually used to treat plague, and this resistance was plasmid mediated.[87]

Patients with pneumonic plague should be considered contagious and placed on respiratory isolation until at least 48 h of effective antibiotic therapy and clinical improvement has taken place.[1]

9.3. Antibiotic Prophylaxis

In circumstances where infection results from rat and flea infestations of houses, drug prophylaxis may be advisable for members of the household and possibly adjacent households, depending on the environmental circumstances. Persons in close contact with infectious pneumonic plague patients during a previous 6-day period should be given postexposure treatment for 7 days. This is both to protect the individual and to prevent further spread. Those who decline drug treatment should be placed under surveillance for 7 days since last exposure. Short-term antibiotic prophylaxis may be recommended in unusual situations for travelers who cannot avoid plague epidemic areas and for health-care workers caring for suspected plague cases in an epidemic situation.

Recommended prophylactic drugs include the tetracyclines for adults and older children and sulfonamides in children younger than 9 years of age; chloramphenicol is also effective.[83]

9.4. Immunization

There are currently no plague vaccines available in the United States. In some countries, living "avirulent" *Y. pestis* organisms are used as immunogens. Studies in the United States have confirmed that such preparations are effective in experimental animals, but none of these is commercially available and their safety and efficacy in humans have not been adequately tested.[10,67,88] Beginning in 1942, a formalin-killed suspension of whole virulent plague bacilli with phenol added as a preservative was used in the United States to vaccinate military personnel and some other persons considered to be at high risk of infection, such as laboratory workers. Different strains of *Y. pestis* were tried, the quantity of organisms per dose was varied, and the dose schedule was altered repeatedly.[88,89] It was not known

which antigens were protective in humans, although recombinant F1 and V antigens were shown to be protective in experimental animals.[66,90,91] The evidence for protection in humans was indirect and weak. In Vietnam during 1961–1971, there were only eight plague cases in vaccinated Americans, while many thousands of cases occurred in the indigenous peoples. US military personnel were undoubtedly exposed to the fleas that transmit plague, since they experienced a relatively high incidence of murine typhus, which is also transmitted by *X. cheopis*.[15,66] Acute and convalescent serum specimens were collected from 59 Americans who had received killed plague vaccine and who experienced clinical and serologically proved murine typhus. F1 antibody was found in the initial serum samples of 39 individuals, and this was attributed to prior vaccination. However, a finding of rising titers or seroconversion in seven patients was interpreted as evidence of subclinical *Y. pestis* infection in persons previously immunized. Experts concluded that the vaccine protected military personnel against bubonic plague during both World War II and the Vietnam conflict.[66] There was no evidence that it protected against pneumonic plague. This vaccine, which had only limited utility, is no longer manufactured in the United States and is not available commercially.

Due to increasing concern that *Y. pestis* could be used as a weapon of terrorism, interest has been renewed in developing a new and improved generation of plague vaccines using molecular methods. The principal approach has been to generate subunit vaccines using a combination of recombinant F1 and V antigens.[67,91,92] These vaccines generate protection by stimulating IgG responses as well as T cell memory. Various recombinant F1 + V combined or fusion subunit vaccines are in advanced stages of development; one formulation has demonstrated both safety and immunogenicity in phases 1 and 2 clinical trials.[92]

9.5. Public Health Management of the Use of Plague as a Weapon of Terrorism

Guidelines on medical and public health management of plague as a biological weapon have been published,[1,2] and various national, state, and local plans are available for responding to bioterrorism and other similar public health emergencies. The critical first step is early detection and recognition that an attack using *Y. pestis* has occurred. Although biosensors are being deployed in special locations and at special events, it is most likely that the first indication of an occult event would be the occurrence of an unusual cluster of cases of severe respiratory illness. Case definitions for illness need to be constructed and disseminated for use by clinicians and epidemiologists for early identification of ill suspects. Since it is expected that the plague organism would be used as an aerosol, heightened surveillance should be instituted for severe respiratory illness, including plague pneumonia and plague pharyngitis. Measures should be taken to isolate and treat all suspected cases at the earliest possible time after onset of illness. Proper infection-control measures would include management of patients under respiratory droplet precautions, with masking of persons who might be at high risk of infective exposures, such as patient care-givers, transporters, and interviewers. The population at risk must be quickly delimited and steps be taken to identify and treat prophylactically during the incubation period those persons who may have had infective exposures at the time of the attack or through direct exposure to infective patients, such as family members and others who have had close and unprotected contact with patients with respiratory symptoms. Treatment should be standardized and taken into account of the possibility of use of organisms with bioengineered antimicrobial resistance. Clear lines of authority and decision-making are critical for a well-organized response, as are advance communications systems and distribution of information necessary to maintain order and effective action.

10. Unresolved Problems

The dynamics of enzootic plague and factors responsible for its introduction, maintenance, spread, or disappearance are not well known. Enzootic foci are widespread and readily available for study, but funding of field research is inconstant. Enzootic plague seems to be dependent on a complex interplay between moderately susceptible and resistant rodents, their fleas, modifications in the landscape, and climate. In the early part of this century, plague was introduced repeatedly into some areas without becoming established in wild rodents; in some areas, enzootic foci have advanced (Western United States) and in other areas they have apparently regressed (India, Indonesia). There are currently no feasible means of eliminating enzootic foci in wild rodent reservoirs.

Despite important advances in understanding molecular factors in the virulence of *Y. pestis*, many questions remain unanswered on pathogenicity of infection in humans. It is not known how plague endotoxin and other virulence factors sometimes cause an irreversible immunologic cascade and death when antibiotic treatment is delayed. Further, clinical trials are needed to examine treatment safety and efficacy of newer antibiotics as compared with streptomycin, tetracycline, and chloramphenicol. The relative rarity of plague in the world today, and the remoteness of the areas where it is

most likely to occur, make it difficult to directly investigate the pathogenesis and treatment response in humans.

Finally, the considerable recent concern over the potential use of *Y. pestis* as a weapon of terror has raised important research questions related to how it might be delivered as a weapon, its public health impact under various circumstances of delivery, the means of early detection and characterization of the agent, and how targeted populations could best be protected, including the use of prophylactic and curative antibiotics and the role of a newer generation of vaccines now under development. The potential for use of an agent resistant to antimicrobials and possibly to vaccines and means to counter this are subjects of study.

Link, V. B., *A History of Plague in the United States of America*, Public Health Monograph No. 26, Government Printing Office, Washington, DC (1955). (Excellent history of the introduction and spread of plague in the United States in the early part of the 20th century, with fascinating descriptions of human plague outbreaks in California.)

Pollitzer, R., *Plague*, *WHO Monogr. Ser*. 22 (1954). (Outdated, but still the most comprehensive plague reference book, with details on the history of plague and documented descriptions of the clinical, epidemiological, ecological prevention and control aspects of plague in the 20th century up until about 1950.)

Wu Lien-Teh, *A Treatise on Pneumonic Plague*, League of Nations Health Organization, Geneva (1926). (A compendium of all information known on pneumonic plague at the time of writing, with descriptions of occurrences throughout the world, and especially the extraordinary Manchurian epidemics of 1910 and 1920.)

CHAPTER 29

Pneumococcal Infections

Keith P. Klugman and Charles Feldman

1. Introduction

The pneumococcus (*Streptococcus pneumoniae*) is the major cause of bacterial pneumonia and meningitis worldwide. In his classic book entitled *The Biology of the Pneumococcus*, published in 1938, Benjamin White[287] listed 19 different names applied to the pneumococcus between 1897 and 1934, the year the designation *Diplococcus pneumoniae* Weichselbaum was approved in the fourth edition of *Bergey's Manual*.[25] In the eighth edition of *Bergey's Manual*,[47] the microorganism was listed as *S. pneumoniae*, the designation that is now generally accepted.

Although any of a large number of microorganisms may cause acute inflammation of the lungs (pneumonia),[110] "typical (primary) lobar pneumonia" is most commonly caused by the pneumococcus. Pneumococcal pneumonia is generally preceded by a simple acute viral infection of the upper respiratory tract such as the common cold and it may also occur as a complication of influenza. It has been called the "captain of the men of death" and "the friend of the aged," because it had long been the principal immediate cause and most frequent contributing cause of death in the aged and infirm and in those with otherwise fatal diseases.

Prior to the introduction of pneumococcal conjugate vaccine, the pneumococcus was also the most frequent cause of acute bacterial meningitis in those over age 3months (Finland, 1977).[239] This remains true today in countries where conjugate pneumococcal vaccine has not been introduced, being exceeded in frequency only should a sporadic meningococcal epidemic occur. In the pre-antibiotic era pleural empyema was one of the most common complications of pneumococcal infection and still remains a common and increasing problem.[52,264,120,83,159,51] In some studies the pneumococcus is the most frequent cause of empyema[111,83,159,51] occurring as a complication of either pneumonia or of otitis media at all ages.[168,30] In one pediatric study the incidence of pneumococcal empyema in children was found to be increasing despite the introduction of the pneumococcal conjugate vaccine.[51] In adults an increase in incidence of pneumococcal empyema may be occurring in association with concomitant HIV infection and in children exact reasons for the increase are not entirely apparent.[264,83,51] In both adults and children this increase appears to be occurring particularly in association with serotype 1 *S. pneumoniae*.[52,264,83,51] The importance of this in the pediatric population is that the current 7-valent pneumococcal conjugate vaccine does not protect against serotype 1, which may account for the findings of Byington and colleagues.[51] Less frequently, the pneumococcus may cause focal infections at other sites in the body. It is also the most common organism cultured from the blood of patients with acute febrile illness, usually pneumonia or meningitis, but not infrequently also from infants and young children with no demonstrable localized site of infection.[198,265,293]

2. Historical Background

The early history of the discovery of the pneumococcus and its pathogenic potential for animals and humans was presented chronologically and in some detail by

Keith P. Klugman • William H Foege Professor of Global Health, Hubert Department of Global Health, Rollins School of Public Health and Division of Infectious Diseases, School of Medicine, Emory University, Atlanta, Georgia, USA; Respiratory and Meningeal Pathogens Research Unit, Medical Research Council and University of the Witwatersrand, Johannesburg, South Africa. **Charles Feldman** • Division of Pulmonology, Department of Medicine, Faculty of Health Sciences, School of Clinical Medicine, Johannesburg Hospital and University of the Witwatersrand, Johannesburg, South Africa.

The first edition of this chapter was written by the late Maxwell Finland and later versions by Robert S Baltimore, and Eugene D Shapiro. The current authors acknowledge the contributions of their predecessors.

White,[287] subsequently, by Finland,[109] Austrian,[14,15] and, more recently, by Watson and Musher.[282] According to Austrian, the pneumococcus was probably first visualized in pulmonary tissues by Klebs in 1875, later by Eberth in 1880, and then by Koch in 1881. However, the organism was first isolated in the laboratory independently by Pasteur in France and Sternberg in the United States and reported by both in 1881; both these workers injected saliva subcutaneously in rabbits, who subsequently died and were shown to have large numbers of organisms in their blood. Pasteur used saliva of an infant that died of rabies; Sternberg injected his own saliva. Thus, both demonstrated the occurrence of the pneumococcus in the pharynges in carriers without relation to disease.

During the next few years, considerable controversy resulted from the descriptions and characterizations of the bacteria seen in pneumonic lungs by Friedlander, Weichselbaum, and Freinkel (quoted by Austrian[14,15]); this was eventually resolved by the application of Gram's stain described in 1884. The stain permitted the differentiation of Friedlander's bacillus, now known as *Klebsiella pneumoniae*, which was decolorized by Gram's method (gram-negative), from the pneumococcus, which was not decolorized (gram-positive).

During the late 1880s, reports were published of the presence of pneumococci in focal infections other than those of the lung, including valvular lesions in cases of endocarditis, purulent meningitis, otitis media, arthritis, sinusitis, conjunctivitis, and from other organs and sites. The syndrome of endocarditis, meningitis, and pneumonia known as Osler's triad has been termed Austrian's syndrome when it has a pneumococcal etiology.[12,81]

At the turn of the century, Neufeld[204] reported on the solubility of pneumococci in bile, which became a useful tool in the differentiation of pneumococci from other streptococci, especially the viridans variety. Most important were the demonstration of the development of antibodies against the homologous pneumococcus following infection or vaccination, which protected animals against subsequent infection with that organism, and the description of the specific agglutination and quellung reactions in homologous antisera by Neufeld[205] in 1902. The agglutination reaction led to the more definite segregation of pneumococci into specific types in 1913 by Lister[179] in South Africa and by Dochez and Gillespie[79] at the Rockefeller Institute in New York.

Some partially successful attempts were made to protect the highly susceptible workers in the gold and diamond mines in South Africa by vaccination with mixtures of these pneumococcal types.[180,215] This also led to the development of specific antisera for therapy and the use of the agglutination reaction to identify the causative type before administering the therapeutic antisera. It was not until 1931, however, that Armstrong[10] in England first reported the clinical use of the quellung reaction for the rapid typing of pneumococci. By 1932, Cooper et al.[66] in New York City had segregated more than 30 specific types; subsequently, workers in the United States and in Denmark increased that number to the 91 types known at present.[220,186,148] Most recently, the genetic sequences of the enzymes that build the capsules of all 91 types have been published.[24,219] The typing of pneumococci and the type-specific antibody response to infection or to immunization, first with whole organisms[292] and later with type-specific capsular polysaccharides,[163] proved to be potent tools that enhanced the capabilities for epidemiological studies of pneumococcal infections[237] and offered the possibility of control of infections in individuals and in susceptible population groups. Unfortunately the radio-immunoassay used to determine serotype-specific antibody responses[237] was first shown in the 1990s to be too non-specific; adsorbed ELISA assays are now the state of the art for measuring pneumococcal antibody.[285]

Meanwhile, progress was being made, notably at the Rockefeller Institute, in delineating the biology of the pneumococcus and its biochemical constituents and immunogenic properties. Most important was the demonstration that the type specificity, pathogenicity (virulence), and eventually also its immunogenicity resided in the specific chemical composition of its capsular polysaccharide. When purified, this component proved to be essentially nontoxic when injected in humans and capable of inducing type-specific antibodies in varying quantities. When it was also shown that 80% of all serious and life-threatening pneumococcal infections, bacteremia, meningitis, endocarditis, and infections of normally sterile body cavities were caused by only 14 of the known 80 or more types, a vaccine incorporating these 14 types was made available,[163] and early trials showed it to be effective in many circumstances. The 23-valent vaccine has been shown in indirect cohort studies to prevent invasive disease, but has not been shown in randomized trials to prevent non-bacteremic pneumonia in the elderly.[157] The great leap forward in the prevention of pneumococcal disease in the new millennium has been the development of conjugate pneumococcal vaccine, which prevents both invasive disease and non-bacteremic pneumonia in immunized children.[28,173,208,71] Through its impact on carriage, this vaccine also has been shown to reduce the burden of invasive pneumococcal disease due to the pediatric serotypes in adults.[288] The effects of the conjugate vaccine on the control of pneumococcal infections are a major subject of contemporary investigation of pneumococcal disease. A separate section of this chapter is devoted to the development

of pneumococcal vaccine and the benefits of its use. Since the late 1970s, there has been concern about the existence of pneumococci resistant to penicillin and other antibiotics.[158] In the 1980s, 1990s, and during the first decade of the 21st century rates of antibiotic resistance have been alarmingly high.

3. Methodology

3.1. Sources of Epidemiological Data

In introducing his chapter on the epidemiology of pneumonia, Heffron[145] indicated that the absolute frequency of occurrence is unknown. Statistics from various health organizations throughout the world provide information on the total number of deaths from all causes, including pneumonia, but in many instances, especially in Africa, where the disease is widely prevalent, deaths are frequently unreported and inaccurate. In the United States, pneumonia and influenza deaths from 121 cities are reported in the Centers for Disease Control and Prevention (CDC)'s *Morbidity and Mortality Weekly Report* (*MMWR*), but they are generally regarded as an index of influenza mortality. As shown in Section 5.15, the role of the pneumococcus in these infections may have been underestimated. In 1934, Collins and Gover[64] reported that acute infections of the respiratory tract caused more deaths and a higher morbidity in the United States than did any other group of diseases. However, it is impossible in the United States or elsewhere to obtain exact figures on morbidity or mortality because pneumonia has not been a reportable disease in most states; it is estimated that even in those states wherein it is reportable, only about half the cases are actually reported. Also, there is no uniform case definition of pneumonia. In temperate zones, lobar pneumonia, but not bronchopneumonia, has a definite seasonal incidence, but their differentiation is often impossible. In the United States, the best estimate of the incidence of pneumococcal pneumonia has come from special surveys (see Section 3.2). The global burden of pneumonia is estimated annually by WHO and it is considered to be the leading infectious cause of death in adults.[289] In children there is evidence that pneumonia causes an increasing proportion of deaths in the poorest countries with the highest rates of infant mortality.[290] Pneumococcal meningitis, while also not a reportable disease, has been included in special meningitis surveys.[56,154,284,239]

3.2. Surveys

A number of surveys have been carried out to estimate the incidence of pneumonia. These include a population study of 2,602,000 people conducted by the federal government for 1935–1963, data from the Cleveland family study reported in 1936, health records from the Kaiser-Permanente Health Center, and reports from hospitals such as the large retrospective regional study performed in Sweden from 1964 to 1980.[49] These have been summarized by Mufson,[200] Austrian,[14,15] and the CDC.[56]

A number of studies have focused on specific populations of interest. Children were the subject of nationwide prospective studies from Finland[87] and Israel.[72] In the United States, specific populations at exceptional risk for pneumococcal infections have been surveyed including inmates of a correctional facility,[151] Alaskan natives,[76] and Native Americans.[67] Data on these populations are presented in Table 1 and discussed in Section 5.1. Antibody surveys have not been reported except when associated with vaccine trials. The assays are not sufficiently specific for use in establishing estimates of incidence.

3.3. Laboratory Diagnosis

3.3.1. Isolation and Identification of the Organism. Growth of pneumococci requires suitable media such as nutrient broth to which serum or defibrinated blood such as that of rabbit, sheep, or horse is added. For epidemiological purposes, however, reliance has been placed on three methods: (1) direct culture on solid media (blood agar); (2) in the past by mouse inoculation;[236] and (3) application of the Neufeld quellung method, latex agglutination, or PCR of the capsular locus to cultures or to fresh materials (sputum, exudate, blood cultures) for specific typing of pneumococci. Agglutination of antibody-coated latex beads has replaced the quellung test in many laboratories for the serotyping of pneumococci, and can be done on CSF for the serotype-specific diagnosis of meningitis[248] and can be used for rapid identification of bacterial colonies in the laboratory by testing blood culture supernatents. Identification of common pneumococcal antigen in urine[234,259] may become a standard in pneumococcal clinical trials and its role in clinical practice is under evaluation. While the assay is specific, it lacks sensitivity and is not useful in children.[88] For cultures of materials from air, dust, skin, or fomites, broth-moistened swabs of the material or surfaces may be streaked directly on blood agar; characteristic colonies of pneumococci are easily recognized after incubation for 12–24 h (as are those of hemolytic or viridans streptococci and staphylococci). The swab may then be placed in blood broth and pneumococci identified from subcultures on blood agar. Initiation of growth of pneumococci may be enhanced by incubation in 5% carbon dioxide or in a candle jar. Additional cul-

Table 1. Focused Studies of the Incidence of Pneumococcal Disease[a]

Years of study	Population surveyed	Size of population surveyed	Incidence (per 100,000), unadjusted	Case-fatality rate (per 100)	Reference
1986–1990	Native Alaskans	81,368	74	13–14	35
1986–1990	Non-native Alaskans	438,763	16	13–14	35

tures in broth, and in the past mouse inoculation, were used to detect multiple serotypes and to enhance the yield. Nasal or pharyngeal swabs may be plated directly on blood agar. Prior exposure to antibiotics (during prophylaxis or therapy) markedly reduces or may eliminate the chance of growing pneumococci from the nose and throat. Carriage studies often use direct plating on blood culture agar plus 5 μg/ml gentamicin to suppress growth of viridans streptococci, but the liquid STGG (skim milk, tryptone, glucose, glycerol) both medium more recently been usedto allow retention of the initial swab inoculum.[209]

3.3.2. Serological Methods. Serological tests for demonstrating type-specific antibodies have included opsonic or pneumococcidal tests in fresh defibrinated or heparinized whole blood, the mouse protection test on serum, macroscopic or microscopic agglutination of heat- or formalin-killed suspensions of organisms, or precipitin and diffusion tests with supernatant fluids of cultures or exudates or with type-specific polysaccharides. These tests differ in sensitivity and also somewhat in specificity. Specific antibody has been quantitated with specific polysaccharides and used in surveys for susceptibility in relation to immunization and to measure the response to conjugate and polysaccharide vaccines. The current gold standard for measuring pneumococcal antibody is enzyme-linked immunoassay (ELISA).[285]

4. Biological Characteristics of the Organism

Morphologically, the pneumococcus typically appears as an ovoid or spherical, coccoidlike form of 0.5–1.25 μm, in pairs, the distal ends of which tend to be pointed or lancet-shaped and surrounded by a distinguishable capsule that contains polysaccharide. The diplococci may occur in chains, particularly in liquid medium, hence the designation streptococcus. The chemical composition of the polysaccharide determines its specific serological type, of which there are now at least 91,[148,220] including several that are closely related serologically, such as serotypes 6A, 6B and 6C. The diplococci usually stain gram-positive, but may decolorize and appear gram-negative in old cultures or after exposure to antibacterial agents. When grown on blood agar, pneumococci form clear, round, mucoid, colorless, umbilicated colonies surrounded by an area of green hemolysis. Heavily capsulated organisms, such as those of type 3, grow in dome-shaped, clear, mucoid colonies.

Resistance of pneumococci to chemotherapeutic agents was recognized as emerging during therapy with ethylhydrocupreine (optochin) in 1918, the first chemical to receive extensive clinical trials in pneumonia.[199] Resistance to sulfapyridine was also recognized as a possible cause of failure of that drug in the treatment of pneumococcal pneumonia in 1938.[286,185] Although significant resistance of pneumococci

to penicillin had been infrequent and limited in geographic distribution in the 1970s and early 1980s, in the past 20 years this has become a serious and increasing worldwide problem (see Section 5.1.1). Resistance to other antibacterial agents has been reported from many areas and has accounted for therapeutic failures. Reports have included resistance to sulfonamides, tetracycline, erythromycin, lincomycin, chloramphenicol, β-lactam antibiotics,[169,7] and more recently the fluoroquinolones.[59] Pneumococci are also relatively resistant to aminoglycosides and some are highly resistant to streptomycin. Multiantibiotic-resistant pneumococci have now been reported globally (see Section 5.1.1).

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In the United States, a federal government survey over a 12-month period in 1935 that involved over 2.6 million people in 83 widely scattered cities and 24 rural counties suggested an incidence rate of 558 cases of pneumonia per 100,000.[14,15] Data from several centers reported for 1920–1928 indicated that deaths from pneumonia generally accounted for 7.4–8.3% of deaths from all causes. On the basis of data from various sources, Austrian[14,15] estimated ("with limited confidence") that the attack rate of pneumococcal pneumonia in the United States lay somewhere in the range of 1.5–10 (more likely between 2 and 5)/1,000 man years of exposure.

The Cleveland study of illness in middle-class families comprising 292 adults and their school-aged children, reported in 1953, has been summarized by Austrian.[14,15] There were three illnesses diagnosed as pneumococcal over a 3-year period, 1974–1976, with an attack rate of 10.3/1,000 man years. At the Kaiser-Permanente Health Center, the estimated attack rate of pneumococcal pneumonia of all types was 1.4/1,000/yearamong Californians 45 years of age or older. However, among institutionalized patients, the attack rate was calculated to be 12.5/1,000/year forpneumonia due to all pneumococcal types.[14,15]

Data on the incidence of pneumococcal infections has come from the CDC[56] and from a detailed review of morbidity and mortality by Mufson.[200] In the early 1980s, the CDC estimated rates per 100,000/year of pneumococcal pneumoniaof 68–260, of pneumococcal meningitis of 1.2–2.8, and of pneumococcal bacteremia of 7–25; the case-fatality rates of these syndromes have been 5–7%, 32%, and 20%, respectively.[56] Mufson's estimates of incidence, converted to rates per 100,000, were 100–200 for pneumonia and 0.3–4.9 for pneumococcal meningitis based on published studies from the mid-1970s. Higher rates of pneumococcal infection were observed in patients with sickle-cell anemia, congenital asplenia, renal transplant, Hodgkin's disease, and multiple myeloma than in subjects without these preexisting conditions.[200]

The importance of *S. pneumoniae* in different clinical syndromes at different ages has been reviewed by Klein[168] in infants and children and by Mufson[200] in the general population. On the basis of recent cooperative studies, the pneumococcus was found to be the most common pathogen cultured from the respiratory tract in infants (other than neonates) and children, and it is also the most frequent cause of serious infections, including pneumonia and bacteremia.[168]

In the general population of nine cities, *S. pneumoniae* was the most common cause of community-acquired pneumonia requiring hospitalization: pneumococcal pneumonia accounted for 26–78% of all pneumonia cases in the nine areas and in most studies exceeded 50%.[200] Mortality rate varied from 6 to 19%, but was two to five times higher in the 20% of adults who developed bacteremia. Indeed, this organism is the most common cause of bacteremia in adults, as well as in children over 1 month old.[200] As shown in Table 1, children and residents of closed communities, such as prisoners and infants, all have a risk of invasive pneumococcal infection far above the estimates for normal populations. While populations can be found with an annual rate of 20 or less per 100,000, children in the first 2 years of life and certain populations such as Native Americans have a much higher rate of illness. In the Israeli study by Dagan et al.,[72] it was shown that within Israel the rate of pneumococcal illness was much higher among the Arab population than among Jews, and the case-fatality rate was 5.7% among non-Jews and 0.3% among Jews.

Pneumococcal meningitis occurs at a rate of about 0.3–4.9 persons/100,000, with children under age 5 years at higher risk.[200] In a summary from the CDC reviewing reports of meningitis from 38 states in 1978, the incidence per 100,000 of *S. pneumoniae* meningitis was 0.30.[55] It was exceeded by *Haemophilus influenzae* meningitis and *Neisseria meningitidis* meningitis, with rates per 100,000 of 1.24 and 0.72, respectively (see Chapters 16 and 23).The incidence of pneumococcal meningitis was highest in the first year of life (age-specific rate of 8.0/100,000). While the absolute incidence is much less in older age groups (0.1–0.4/100,000), its *relative* importance increases, and this organism is the most common cause of meningitis

for elderly individuals in the United States. In a CDC-sponsored study of six states surveying 34 million people in 1986, the incidence of pneumococcal meningitis was 1.1 per 100,000 compared with rates of 2.9 and 0.9 per 100,000 for *H. influenzae* and *N. meningitidis*, respectively.[284] With the dramatic decline of *H. influenzae* meningitis in the early 1990s due to the success of the conjugate vaccines, prior to the introduction of conjugate pneumococcal vaccine *S. pneumoniae* was the most common cause of bacterial meningitis.[239] In a study of children from Israel, 1988–1990, the rate of pneumococcal meningitis was 5.4/100,000 for children less than 5 years of age, but in infants less than 1 year of age it was 16.7/100,000.[72] In Finland, 1985–1989, the rate of pneumococcal meningitis was 2.1 per 100,000 for those under 5 years of age and 6.8/100,000 for those under 1 year of age.[87] *S. pneumoniae* is also the most common aerobic organism grown from blood of febrile infants and children in whom no focus of infection is determined. The highest rate of pneumococcal carriage in the United States is also among preschool children; it is somewhat lower in older children and is about the same in adolescents as in adults, but in the last two groups, carriers are more frequent in households with preschool children.

The commonest pneumococcal infection is pneumococcal otitis media of which there are thought to be approximately 7 million infections per year in the United States alone, with more than 60% of infants experiencing at least one episode of otitis media during the first year of life (Teele, Lein et al., 1989).

5.1.1. Occurrence of Penicillin-Resistant Pneumococci. Penicillin has historically been the antibiotic of choice for most cases of pneumococcal infection. There has been monitoring of pneumococci worldwide for susceptibility to this agent, and in the past, growth of pneumococci has generally been inhibited by a concentration of less than 0.05 μg/ml of penicillin. Relatively resistant strains (now referred to as intermediately resistant) had been reported with low-frequency prevalence worldwide since 1967 when a well-documented case of respiratory infection due to a pneumococcal strain with an MIC of 0.6 μg/ml of penicillin G was reported from Sydney, Australia.[138] The patient involved was a 25-year-old with hypogammaglobulinemia and bronchiectasis who had received many courses of antibiotic treatment in the past. Since then there have been many reports of such isolates. Until the 1980s, there were only sporadic reports of strains intermediately resistant, with MICs of 0.1–1.0 μg/ml to penicillin. Strains resistant to 2.0 μg/ml of penicillin are termed high-level resistant strains using meningitis breakpoints. The Clinical Laboratoy Standards Institute (CLSI) has recently published new breakpoints for pneumonia of intermediate susceptibility at 4 μg/ml and resistance at 8 μgml for treatment with parenteral penicillin.

Beginning in South Africa in 1977,[8,158] there have been reports of pneumococcal isolates resistant to penicillin, using meningitis breakpoints with MICs at 2–16 μg/ml. These strains generally had resistance to multiple antibiotics including tetracyclines, streptomycin, chloramphenicol, erythromycin, clindamycin, and sulfonamides. Only a small number of pneumococcal serotypes have been associated with high-level resistance. Generally, the level of resistance to penicillin correlates with resistance to all semisynthetic penicillins and cephalosporins.[7] Resistance of pneumococci has not been associated with the production of β-lactamases but with the alteration in the cell-membrane-associated enzymes that are responsible for cell wall assembly and that bind penicillin. Alteration of these penicillin-binding proteins has been associated with high-level resistance[295] as well as low-level resistance,[137] and penicillin tolerance.[53,271] (Penicillin tolerance refers to strains requiring a substantially higher concentration of penicillin to kill them than to inhibit their growth.) Strains of pneumococci can develop increasing resistance in a stepwise fashion,[53] and the genes for altered penicillin-binding proteins may come from heterologous organisms as well as pneumococci.[271] It appears that resistant clones have spread throughout the world, although the rates of resistance vary considerably in different countries. Global-resistant clones are now defined by the Pneumococcal Molecular Epidemiology Network.[196]

The outbreak of multiply-resistant pneumococci that began in Johannesburg, South Africa, in 1977, deserves special mention. The first isolate was a serotype 19A from the sputum of a hospitalized 3-year-old with pneumonia. Additionalisolates were recovered by screening patients and hospital personnel from the same hospital using an agar-disk diffusion method for screening pneumococcal respiratory isolates. It was clear that these were virulent strains as there was considerable morbidity and some deaths attributable to invasive infection due to these pneumococci. These isolates were resistant to penicillin concentrations of 0.12–4 μg/ml and were found in 29% of 543 pediatric patients and 2% of 436 hospital staff members.[158] The year 1977 appeared to be a watershed year as resistant pneumococcal strains were reported from Durban, South Africa; Minneapolis, Minnesota; and London, England.[158] The report from Durban involved five cases of meningitis or sepsis in children from 3 months to 2 years of age. Each had severe malnutrition, with recent courses of antibiotic treatment. Three cases occurred while the children were hospitalized and receiving antibiotics. The isolates were serotype 19A and had MICs of 4–8 μg/ml of penicillin and exhibited resistance

to other β-lactams, aminoglycosides, and chloramphenicol. The three children with meningitis died and the two with septicemia responded to treatment with alternative antibiotics.[8]

Intermediately susceptible strains (penicillin MICs 0.1–1 μg/ml) are clearly less susceptible than are usual strains, but in the absence of meningitis, infections due to these strains are often successfully treated with high doses of penicillin.[53,217] A prospective study of 504 patients in Spain demonstrated a similar outcome in patients treated with penicillin or cephalosporins whether their pneumococcal isolate was fully susceptible to penicillin or less susceptible.[217] There have been a number of recent reviews which conclude that intravenous penicillin and highly active intravenous cephalosporins such as cefotaxime and ceftriaxoneare adequate therapy for intermediately resistant pneumococcal pneumonia.[172,226] These data support the higher breakpoint (4 μg/ml) for clinically relevant resistant infections outside of the CNS. High doses of intravenous penicillin or ceftriaxone provide adequate drug concentrations above an MIC of 4 μg/ml for at least 40–50% of the dosing interval (ceftriaxone given twice daily). Macrolide-resistant strains do not, however, respond to macrolide therapy[183](Daneman, McGeer et al., 2006), nor do fluoroquinolone-resistant strains respond to treatment with those agents.[77]

The cause of the increase of antibiotic resistance is multifactorial. There is abundant evidence that prior exposure to antibiotics is a risk factor for infection due to resistant strains and may play an important role in rising rates of resistance.[9,36,279] The exceptional risk of children and the high prevalence of "pediatric" serotypes among resistant strains (serotypes 6, 14, 19, 23) provide evidence that indiscriminate use of antibiotics for minor pediatric infections may be a major factor driving this epidemic.

5.1.2. Distribution of Pneumococcal Types. The importance of pneumococcal types and their distribution in various populations need to be stressed. In the past, when immunotherapy with type-specific serum was used, typing of organisms and provision of the proper sera required knowledge of the prevalent serotypes. Since the introduction of the pneumococcal polysaccharide and conjugate vaccines, which induce type-specific immunity, it is now necessary to know the prevalence of pneumococcal serotypes in order to prepare an appropriate multivalent vaccine. Because the frequency of the different serotypes varies with time and with different clinical syndromes,[112,115] constant monitoring continues to be a necessity for inclusion of the appropriate types in vaccine formulations.[21] There has been a fundamental shift in the serotype distribution of pneumococci causing invasive disease in adults in the United States with an increasing prevalence of pediatric serotypes (mainly 6A, 6B, 9V, 14, 19A, 19F, 23F) and a great reduction in disease due to the classic types 1, 2, and 5.[92] The distribution of pneumococcal serotypes causing invasive disease in children has been recently reviewed.[140,141,92,142] It is clear that immunocompromised patients[118] and patients infected with HIV[68,102,118,48] have an increased proportion of pediatric serotypes and these pediatric strains increase in frequency in adults > 65 years of age.[93]

Pneumococci have been classically serotyped according to the presence of specific carbohydrate antigens that make up the capsule of the bacterium. Rabbit antisera specific for each serotype are used. There have been two serotype designation schemes used, the Danish and American systems.The Danish system is now dominant and classifies strains with a number designation and sometimes a letter following the number. A serogroup number represents a group of antigenically related strains. Each type within the group is indicated by a suffix letter (e.g., serogroup 6 contains serotypes 6A, 6B, and 6C). The propensity of a given serotype to cause invasive disease varies greatly and a ratio of invasiveness has been established.[43] Multiple types of pneumococci can be isolated from infected patients and carriers at the same time or at different times and may persist for varying lengths of time, continuously or intermittently in carriers as well as after recovery from pneumonia. The role of these types of infections in the individual patient may be surmised from the clinical findings of the demonstration of antibodies to the homologous types during the infection or convalescence. The serotypes present in the current vaccines and those most commonly encountered in bacteremic pneumococcal diseases of adults and children are summarized in Tables 2 and 3

from several sources. These change with time and place, so that individual reports may vary from the data shown. In the United States and most Western countries the most common serotypes encountered in adults are 3, 4, 7, 8, and 14[14,15]while in children the most common serogroups/types are 6, 9, 14, 19, and 23. Types 1 and 5 continue to be reported frequently in developing countries.[140,141] Tables 2 and 3 demonstrate that (1) the 23V vaccineincludes the types most commonly responsible for bacteremic disease in children and adults; (2) there is broad overlap in the serotypes seen in children and adults but some differences exist; and (3) bacteremic diseases in immunocompetent adults are largely due to serotypes with lower numbers; the higher-numbered serotypes are more commonly found in the pharynges of healthy carriers. In the era of conjugate pneumococcal vaccine, the pediatric serotypes are disappearing among both children and adults with replacement disease occurring in a number of serotypes, particularly type 19A.[22]

5.1.3. Occurrence in Carriers. Pneumococci are present in the nose or throat or both of about one fourth of all healthy persons at any given time; they are more prevalent in the winter months, and nearly all individuals carry them transiently or intermittently in the course of a year. In very young (<2 months of age) infants, they are usually found only if they occur in the mother, but in older infants, they are more frequent.[209] Mothers who smoke have increased pneumococcal carriage as do their infants.[136] The frequency of colonization in the very young is correlated with crowded poor socioeconomic living conditions such that 50% of children in aboriginal communities are colonized by 6 weeks of age[176] while it takes 6 months for a similar level of colonization to occur in US children.[134]

The presence of upper-respiratory infections is not ordinarily a determinant in the individual, but epidemics of respiratory infections tend to increase the spread of disease-producing types of pneumococci, particularly in families of cases.[75]

The epidemiology of pneumococcal infections was discussed in some detail at a symposium on the *Pneumococcus*[228] in 1980 in which Riley and Douglas from Papua New Guinea likened the situation in their country to that in the New World at the turn of the century.[231] Acquisition of pneumococci in the nasopharynx begins in infancy, reaches the highest rates in preschool children, and then declines in advancing age groups. The rates in New Guinea, as elsewhere, are generally related to the amount, degree, and duration of contact with cases or other carriers.

5.2. Epidemic Behavior and Contagiousness

As early as 1888, Netter[203] presented evidence, mostly on clinical grounds, for the contagiousness of pneumonia and for the part played by the pneumococcus. He described family outbreaks of pneumonia and other pneumococcal infections even in the same household. He and others[69,161] traced cases to direct or close contact with other cases or convalescents. He found that pneumococci survived in dried sputum for many months and he recovered the organisms from the dust of hospital rooms.

Epidemics involving multiple cases in families[114,42] or in institutions[251,252] were described in which direct contagion was traced either separately or during outbreaks in small communities. In some of them, the pneumococcus was identified by culture or mouse inoculation.[273] Outbreaks of focal pneumococcal infections have been recorded both in association with pneumonia and independently. Pneumonia acquired in foundling homes was recognized early on as an important cause of high death rates in infant asylums and as a frequent cause of deaths in babies who were healthy on arrival. Direct contagion was also recognized as the cause of the spread of pneumonia among workers in mining camps in South Africa,[132,215,213,214] as well as during the construction of the Panama Canal[145] in which overcrowding, especially

in sleeping quarters, and high attack rates soon after arrival were the two most important features.

Pneumonia was the leading cause of death in army camps during the Anglo - Boer War of 1899 – 1902 and World War I,[273,63,250,218] and occurred mostly in relation to epidemics of measles and influenza associated also with hemolytic streptococci, but the majority of cases and deaths after and even during such epidemics were typical pneumococcal lobar pneumonia. In 1919, epidemics of type 1 pneumococcal pneumonia were reported from Camp Jackson[218] and Camp Upton[266] and of type 2 from Camp Grant.[149] New draftees and black recruits were the most susceptible. Direct contagion was later demonstrated when typing was used. In 1940, spread of pneumococcal pneumonia could also be traced in some hospitals from bed to bed.[152] In 1937, Harris and Ingraham[139] described an epidemic of type 2 pneumonia in the Civilian Conservation Corps confirmed in many cases by serological studies; these involved primarily members of the corps in the same barracks and only two officers who had the most contact with the men. Reports have stressed smaller epidemics and nosocomial spread of resistant strains;[8,158,247] the association of pneumococcal disease with influenza;[200] and conditions responsible for greater susceptibility to pneumococcal infection (see Section 7.1). An outbreak of pneumococcal pneumonia in a jail reinforced the importance of overcrowding and poor ventilation as contributing factors.[151] Epidemics of meningitis separate from pneumonia have recently been described in Africa, although the pneumonia burden was not quantified.[177]

5.3. Geographic Distribution

As already noted, reliable information on the geographic distribution, prevalence, and incidence of pneumonia and particularly of other pneumococcal infections is unknown because of lack of adequate reporting in most parts of the world and the unreliability of those reports that are available. It may be said, however, that such infections are ubiquitous worldwide, and endemic and, under some conditions, may occur in well-circumscribed epidemics. Although usually thought to be particularly prevalent in temperate zones, they also occur in warmer regions and in the tropics.[145] Temperature and humidity appear to influence the prevalence of pneumonia, and in countries where the most abrupt and severe changes occur in winter, the incidence of the disease is correspondingly high during such times.[135,233]

Among admissions to the Boston City Hospital, the incidence of pneumococcal bacteremia[197] and meningitis (Finland 1977) decreased after 1935 and again after 1941 with the general use of sulfonamides and penicillin, but it fluctuated within a moderate range after that. The case-fatality rate after 1941, however, still remained high in cases of meningitis and varied with age in other bacteremic cases, being highest in infants and in persons 70 years or older.

5.4. Temporal Distribution

Although the low numbered serotypes dominate reports of invasive disease in both children and in adults, during the early part of the 20th century, over the course of the century the higher numbered pediatric serotypes became more common reflecting perhaps a shift from direct contagion, to disease caused by circulating carriage types in the very young and the very old, as well as in immunocompromised persons in middle age.[93]

5.5. Age

Pneumococcal infections occur at all ages, although they occur more commonly at extremes of age (Jokinen, 1993). They are most frequent in the first year of life, decrease rapidly to a low between 10 and 15 years, and then increase in incidence steadily in advancing age groups. Deaths from such infections are also most frequent in the first year of life, least frequent between 15 and 20 years, and rise with advancing age groups more steeply than do the case rates.[145] A change has been noted in the age of adult patients with invasive pneumococcal infections in association with the HIV epidemic. HIV-seropositive patients with invasive pneumococcal infections, including pneumonia, are usually found to be younger than HIV-seronegative cases.[162,101] The estimates of incidence for invasive pneumococcal infection in Goteborg, Sweden, which are typical of a developed country, are 25.8/100,000 in the first year of life, falling to 2/100,000 in the second decade, then rising by decade and peaking in the eighth decade at 16.4/100,000.[49] The case-fatality rate from pneumonia and meningitis increases with each decade, from under 10% in the young to over 50% in the eighth decade. The age distribution of cases of pneumococcal meningitis followed the same trend among patients at Boston City Hospital during 12 selected years between 1935 and 1972, but the case-fatality rates were higher, about 60%, for those in the first decade of life, 50% in the second decade, and increased with each decade thereafter to 81% in patients 70 years old or older (Finland, 1977). It is not just increasing chronological age that predisposes to pneumococcal disease, but also the increasing frequency of the underlying comorbid conditions associated with older age.[94]

5.6. Gender

Among cases of lobar pneumonia occurring in Massachusetts between 1921 and 1930, males predominated over females (58/42) in all age groups, but male predominance was less among infants and young children.[145] Among bacteremic patients at Boston City Hospital in 1972, the ratio was 51.7% males and 48.3% females for all patients.[197] The ratio of males to females among cases of pneumococcal meningitis for the 12 selected years between 1935 and 1972 (Finland 1977) was much higher and averaged 65% male for all ages, but varied in different age groups: 67% males among infants (<1 year old), 78% males in those 1–9 years old, 100% males among the small number of 10–19 years, and dropping steadily with each decade to 50% males among patients 70 years or older. Concomitant with the HIV epidemic changes have been noted in the gender ratio. Studies comparing HIV-seropositive and HIV-seronegative cases with bacteremic pneumococcal pneumonia have noted a greater number of female patients among the HIV-seropositive patients.[101,48]

5.7. Race

It has long been recognized that black people are peculiarly susceptible to pneumonia when they reside in cold climates, especially when moved from warm tropical regions. Under certain conditions, there is also a pronounced susceptibility in black people to pneumonia and pneumococcal infections in general even in warm climates. For example, high rates were encountered among the construction workers, who were predominantly black, during the building of the Panama Canal and among pneumonia patients elsewhere in Central America and tropical Africa.[145] Death rates from lobar pneumonia in various widely scattered states in the United States are also considerably higher in black people, sometimes twice as high as among white people. Thus, while true genetic susceptibility has not been separated from socioeconomic factors, black people are most likely to be subject to crowding in occupational as well as residential life (which is related to risk of infections), and may have a higher incidence of certain lifestyle risks[200,151] and reduced availability of medical care. Rates of invasive pneumococcal disease are also higher in indigenous communities such as Alaskan communities.[147]

5.8. HIV Infection

HIV infection itself is a significant risk factor for pneumococcal pneumonia.[91] While the exact mechanism(s) predisposing to pneumococcal infections are uncertain a number of studies have investigated possible reasons.[242,274,202,82] Impaired natural immunity to pneumolysin may be an important factor predisposing to bacteremic pneumonia.[3] Impaired opsonic activity of type-specific IgG in HIV-1 infected Ugandan adults appears to predispose these individuals to invasive pneumococcal infections.[262] Many risk factors for pneumonia in HIV-seronegative patients, such as comorbid illness, cigarette smoking, previous pneumonia, alcoholism, cirrhosis, neutropenia, low serum albumin, also predispose HIV-seropositive patients to pneumonia.[242,274,202,82] Conversely, factors associated with a lower risk for pneumonia in HIV-seropositive patients include pneumococcal vaccination, co-trimoxazole prophylaxis, and the introduction of highly active antiretroviral therapy.[91]

5.9. Cigarette Smoking

It has been known for a long while that cigarette smoking predisposes patients to community-acquired pneumonia.[2,206,207] Cigarette smoking has a number of detrimental effects on both immune and non-immune defence mechanisms in the human. Abnormalities induced by cigarette smoking that may predispose individuals to pneumonia include impaired mucociliary function, effects on immunoglobulin production and function, macrophage function, maGophge function, and effects on macrophage, polymorphonuclear leukocyte, and lymphocyte function. There is a specific risk for pneumococcal pneumonia in smokers[206,207] and cigarette smoking appears to be an independent risk factor for invasive pneumococcal infections. These investigators documented that the risk of pneumonia showed a positive trend with increased duration of smoking, increased number of cigarettes smoked, and the cumulative consumption of cigarettes.[206,207] Similarly HIV-seropositive patients who smoke cigarettes and/or drugs are also at increased risk of pneumonia.[98]

5.10. Occupation

Pneumonia has been known to be unusually prevalent in certain mining and milling industries.[44] In some mills, this has been associated with a high carrier rate that has been followed by an outbreak of pneumonia in the community.[129] In certain mining regions, the living conditions of the workers themselves, rather than the circumstances surrounding the work, may be the determining factor in spread of the disease. This was true in a group of steel workers who were crowded into small shanties in 1917,[261] among workers and their families during the construction of the Panama Canal in

1913,[132] among miners in South Africa,[211,215,182,212] and among plantation workers.[84]

The high attack rate in South African miners may occur because of the social environment of the gold mines. The community regularly receives non-immune recruits who have lived in remote rural areas and not been previously exposed to invasive pneumococcal serotypes/groups. The organisms spread rapidly through the closed communities and these recruits are at increased risk of pneumonia for approximately 6 months after recruitment.[128] This has sometimes been referred to as "recruit" disease.

5.11. Occurrence in Families

Today little attention is paid to the spread of pneumococcus within families, and the occurrence of a single case of invasive disease in a family does not merit the attention and use of prophylactic antibiotics that cases of meningococcal or *H. influenzae* disease do. Nevertheless, since prolonged intimate contact is required for spread of the pneumococcus, it is not surprising that spread in families does occur. Heffron[145]mentions a number of reports of multiple family members being infected with the same serotype of pneumococcus. In some cases affected family members were carriers, but in many there was an outbreak of invasive infections. The occurrence and spread of pneumococcal infections among members of the households of patients admitted to Boston City Hospital with lobar pneumonia were reported by Finland and Tilghman[114]and by Brown and Finland.[42] They included multiple cases of infections with the same type as the index case; some had lobar pneumonia and others had empyema, primary pneumococcal meningitis, otitis media, simple upper-respiratory infections, or bronchopneumonia, or were carriers without evidence of infection. Some cases admitted with lobar pneumonia were traced to contacts with other cases already in the hospital, but not from the same household. Serological studies demonstrated the presence or development of antibodies to the same types. The appearance and spread of additional new types among members of the household were also noted; these were also associated with pneumonia or focal infections or mild upper-respiratory infection and with the development of specific antibodies to the homologous types in a large percentage of members of these households. The advent of molecular typing allows the study of pneumococcal spread within families at the level of the clone within serotype. Spread of clones within families has been addressed in two recent studies. In the first, the index case was a child in day care and little spread of strains was demonstrated from children to their parents, suggesting a biological barrier in transmission between children and healthy adults.[230] On the other hand, a study from Japan showed that when the index case is an adult susceptible to pneumococcal disease (i.e., an infected adult), the pneumococcal strain causing that infection can often be found circulating among the children in the family.[153]

5.12. Occurrence in Animals

The occurrence of pneumococcal carriers and of widespread epidemics of pneumococcal infections among animals was reviewed by Finland.[109] They probably play very little or no part in infections and outbreaks in humans beyond causing occasional cases among animal handlers and will not be considered here.

5.13. Laboratory Infections

Cases of pneumonia acquired in the laboratory are not frequent. They have been associated with exposure to aerosols[232] or droplets or with handling of sputum.[23] They are of interest in delineating the incubation periods of pneumonia in man, since the clinical evidence of infection was manifest from 36 h to 3 days after a single exposure. Various types, including 1, 2, 7, and 18, were involved, and the same individual has been subject to more than one attack, but with different types and at different times.

5.14. Nutrition

The effect of specific nutritional deficiencies in predisposing to pneumonia is not known. Undernutrition, particularly of calories and proteins, is recognized as predisposing to infectious diseasesin general (see Chapter 1). There appears to be a greater risk of pneumonia in patients who are malnourished or have a low body mass index. Deficiencies and abnormality in cellular and circulating immune factors (e.g., complement) may play a role.[277] However, in contrast, one study undertaken in the United States investigating the relationship of lifestyle factors to the occurrence of community-acquired pneumonia noted a direct relationship between body mass index and the occurrence of pneumonia in females.[20] In both men and women in that study, an increase in weight of 40 lbs or more($\geq$ 18 kg) was associated with a twofold increase in the risk of pneumonia compared with individuals who maintained their weight.

5.15. Alcoholism

Alcoholism has been regarded as a major predisposing factor for invasive pneumococcal infections. In a Swedish study it was the most important risk factor in adults.[49] In

a US study, alcoholics also had a higher fatality rate from pneumococcal sepsis than did nonalcoholics, but only when accompanied by leukopenia.[225] The mechanisms of susceptibility of alcoholics to pneumonia are numerous and include factors such as enhanced oropharyngeal colonization, impaired mucociliary clearance, increased aspiration risk, defective surfactant production, decreased pulmonary function, macrophaye functionand effects on both humoral and cellular immunity.[95,96]

5.16. Association with Viral Infections

There are abundant lines of epidemiological, biological, and animal experimental evidence that pneumococcal infections occur more commonly and are of increased severity when they occur together with viral respiratory infections, including influenza.[224] The cough and mucus secretions associated with these infections may be important enhancers of pneumococcal spread in communities.[45] Recently it has been possible to determine the frequency of pneumococcal co-infection with viral respiratory pathogens by using conjugate vaccine (see Section 9.3 below) as a probe. These studies have documented that more than 40% of influenza hospitalizations for pneumonia in children,[188] similar percentages of RSV and parainfluenza infections,[188] and more than 50% of human metapneumovirus infections[191] leading to emergency room visits and hospitalization, are complicated by conjugate vaccine-preventable pneumococcal infection.

6. Mechanisms and Routes of Transmission

The most common route of transmission of pneumococci is by droplets from cases and carriers. In hospitals, the most frequent spread is from one patient to the patient in the adjacent bed, the disease rarely skipping a distance of more than two beds. Physicians, nurses, attendants, and others with frequent and close contact with patients are subject to colonization or infection from the patients unless they take special precautions to avoid or reduce exposure to the patients' droplets (coughing and sneezing), such as by masking the patient or themselves or both. Although pneumococci may becultured from the air or from the dust on the floors or in the rooms of patients with pneumonia they remain viable in dried secretions for long periods, probably as long as many days if not in direct sunlight.[287,145] Documented infections from such sources are rare.

In cases of pneumococcal meningitis following skull fractures, the infecting organism comes from the patient's own nasopharynx or accessory sinuses, and these foci are probably the sources of "primary" pneumococcal meningitis. The route by which the organism reaches the meninges in "primary" cases can often be traced to previous head trauma involving small fractures in the cribriform plate which may be difficult to recognize on X-ray. Suchfractures may be associated with recurrent pneumococcal (and other bacterial) meningitis that no longer recurs after the defect in the cribriform plate has been repaired. As the route of infection is directly from the nasopharynx, it is possible that serotype replacement in the conjugate vaccine era may be associated with more evidence of replacement in meningitis than in bacteremia, which is associated with a more restricted range of pneumococcal serotypes.

Otitis media in the acute form, and probably also acute sinusitis, usually occurs during or after simple upper-respiratory tract infections and is caused by the same type of pneumococcus found in the nose and/or pharynx or both. Experimentally, inflammation associated with occlusion of the eustachian tube (produced by influenza virus) is required to produce otitis media in the chinchilla after colonization of the nasopharynx with pneumococcus.[123,121]

7. Pathogenesis and Immunity

7.1. Pathogenesis

The incubation period for pneumococcal pneumonia is not known. Most sources state that it is 1–3 days. Heffron[145]suggests that it is "in the neighborhood of a few hours to about 48 hours". This would be for an infection from an exogenous source. Endogenous infection in a person who was previously an asymptomatic carrier and then developed invasive disease can occur with an "incubation period" of weeks, but in many cases infection as suggested above may follow a relatively short time after an upper-respiratory tract viral infection.

While significant details of human immunity to the pneumococcus are known, the exact mechanisms by which it multiplies in tissues and produce local inflammation or invasive disease remain to be fully elucidated. Pneumococci attach to respiratory epithelial cells by interaction with cell surface receptors. Mouse, rabbit, rat, and dog, and probably also humans, can remove large numbers of inhaled virulent pneumococci. This is done in part by the ciliated epithelium of the trachea and bronchi but in greater measure by the phagocytic cells, predominantly the pulmonary macrophage system, and is effected with or without the mediation of humoral antibodies.[164] It is known that damage to the ciliary system by alcohol or other inhaled toxic substances such as cigarette smoke or by minor viral respiratory

infections is necessary to establish pulmonary infection by pneumococci. In experimental animals, intrabronchial inoculation of pneumococci in a gelatin or starch plug is necessary to establish pneumonia, which extends out from the local alveoli to other parts of the lung.[65] In the dog, infection occurs in the local alveoli, and the pneumococci appear very rapidly in the local lymphatics, then in the hilar lymph nodes, then in the thoracic duct and subclavian vein, and finally in the peripheral blood.[80,267] The healthy mouse, in which a single virulent (e.g., type 1) pneumococcus injected intraperitoneally produces a lethal infection, can inhale a large number of the same organism from an aerosolized culture without ill effect; but the same aerosol will produce bronchopneumonia, bacteremia, and death if inhaled after the mouse has been anesthetized. Intranasal instillation of the broth culture will also produce pneumonia and death in the mouse[258] and in the rabbit.[257] A dermal pneumococcal infection has been produced by intradermal inoculation in rabbits; this lesion can be prevented by previous immunization and terminated by specific antiserum.[131] The same is true of experimental infections in the mouse and the dog. The importance of inflammation and obstruction of the eustachian tube for the establishment of pneumococcal otitis media was mentioned in Section 6.

7.1.1. Virulence Factors. The pathogenesis of pneumococcal infections is complex and involves the interaction of multiple possible virulence determinants with each other and with the immune system of the host.[61] These have been extensively reviewed elsewhere together with the biology of the pneumococcus and the molecular basis of pneumococcal disease.[70,272,184]

7.1.1.1. Capsule. The pneumococcal-specific capsular polysaccharides are complex polysaccharides, and the chemical structures of many have been elucidated in detail. These polysaccharides are responsible for the type specificity of protective antibodies that are elicited during infection[113] and the serological classification, which can be determined by the quellung reaction. The presence of the capsule is required for a strain to be pathogenic, and a larger amount of capsule production is associated with increased pathogenic potential. As with other encapsulated organisms, the primary pathogenetic role of the capsule is to allow the organism to avoid phagocytosis by leukocytes. By itself the capsule does not elicit inflammation.[275] There is some clinical and laboratory evidence that when the concentration of free polysaccharide antigen in the blood is very high, there is spontaneous activation of complement that could result in disseminated intravascular coagulation and shock.[235,124]

7.1.1.2. Cell Wall. The cell wall component of the bacterium appears to play an important role in pathogenesis.[275] Components of the cell wall stimulate the recruitment of leukocytes, enhance endothelial permeability, which leads to local edema formation, and induce the production of cytokines. Thus, cell wall components may be responsible for the pathological picture characteristic of pneumococcal pneumonia and meningitis. Consistent with this model is the belief that treatment with antibiotics that cause cell lysis is associated with the release of cell wall components that may temporarily augment the inflammatory response.[275]

7.1.1.3. Surface Proteins. These include PspA and PspC. The former is a surface protein found on all pneumococci that has been shown to be required for full virulence of pneumococci.[34,35] The function of PspAappears to be to reduce consumption of complement by pneumococci which may lead to reduced complement-mediated phagocytosis and clearance of pneumococci. The importance of these surface proteins is that they are highly immunogenic and it has been suggested that they may represent possible ideal protein candidates for alternative pneumococcal conjugate vaccines.

7.1.1.4. Cell Wall Hydrolases/Autolysins. The cell wall autolysins, in particular lytA, are important for the virulence of pneumococci. The mechanisms by which these enzymes contribute to pathogenicity are first by releasing cell wall breakdown products, which, as described above, are known to elicit a wide range of proinflammatory activities, in the host. Second these autolysins release pneumolysin, which is a cytoplasmic protein, released into the external medium when pneumococci undergo autolysis, and which, as described below, is considered to be one of the most important virulence factors of the organism.[221,184]

7.1.1.5. Toxins. The microorganism also has a number of toxins, including pneumolysin, hyaluronidase, neuraminidase, and IgA 1 protease. One of the best studied toxins of the pneumococcus is pneumolysin, a thiol-activated pore-forming toxin.[62] Pneumolysin is a protein consisting of 471 aminoacids and is produced by all clinically significant isolates of pneumococci. It has a number of significant activities that appear to play an important role in the pathogenesis of pneumococcal infections. The toxin has the ability to slow ciliary beating[103,105] and subsequently cause damage to the structural integrity of the ciliated epithelium. The slowing of ciliary beating appears to aid initial colonization of airway epithelium with subsequent invasion occurring following damage to the airway epithelium. Recombinant pneumolysin has also been shown in an experimental model to induce the salient histological features of pneumococcal pneumonia in the rat lung in vivo.[104] The toxin also interacts with a number of components of the hosts' immune response, as described below,[62] which may also play a role in the pathogenesis of pneumococcal infec-

tions. For example, the toxin has been reported to induce apoptosis in a number of cell types, including neutrophils, macrophages, and neuronal cells, which may contribute to persistence of the pathogen. In sub-lytic concentrations the toxin also has been reported to possess a wide range of proinflammatory activities, involving primarily neutrophils and macrophages/monocytes and their inflammatory mediators. Importantly it has recently been reported that exposure of neutrophils to pneumolysin was accompanied by influx of Ca^{2+}, activation of NFkappaB, and synthesis of IL-8.[63,107] Based on several experimental studies, these proinflammatory activities appear to be operative in vivo.

Among the other toxins produced by the organism, hydrogen peroxide (H_2O_2) has also been shown to cause slowing of ciliary beating and damage to the structural integrity of the ciliated epithelium, which neither enhances nor antagonizes these same effects induced by pneumolysin.[99]

Virtually all strains of pneumococci produce hyaluronidase which is said, because of its ability to degrade connective tissue, facilitates tissue invasion by the pneumococcus. This toxin is therefore sometimes called the "spreading factor". However, hyaluronidase also enhances the ciliary slowing and epithelial dysfunction induced by pneumolysin.[100] In addition, it has been said to be able to breach the blood–brain barrier, and both human and experimental studies suggest it plays an important role in the pathogenesis of pneumococcal meningitis.

One or more neuraminidases appear to be produced by clinical isolates of pneumococci, which have been thought to play an important role in the pathogenesis of pneumococcal meningitis. These enzymes have the ability to cleave sialic acid residues from a wide variety of glycolipids, glycoproteins, and oligosaccharides on cell surfaces which might unmask receptors for putative pneumococcal adhesins.[221]

7.1.2. Host Defenses. In humans, host defenses against the pneumococcus can be divided into natural and acquired. Some of the natural host defenses have been deduced from experimental studies, but to a large extent they have been inferred from high rates of disease in people with underlying (predisposing) abnormalities.

The natural defenses in individuals with normal lungs include the transport of bacteria out of the lungs by the coordinated motion of the cilia and the production of an inflammatory response.[95,96] Damage to the lungs by previous infections, smoking, bacterial toxins (as described above), occupational exposure to lung toxins, or chronic obstructive pulmonary disease is associated with defective clearance by these mechanisms and therefore is associated with enhanced susceptibility to infection by *S. pneumoniae*.

Humoral immunity is of considerable importance in acquired resistance to infection with the pneumococcus. Individuals whose B-cell function is abnormal are predisposed to infection on this basis. This includes infants, children, and adults who have congenital B-cell deficiency and hypogammaglobulinemia. This predisposition can be ameliorated by treatment with intramuscular or intravenous gamma globulin every 3–4 weeks. Acquired dysgammaglobulinemias including multiple myeloma and acquired immunodeficiency syndrome (AIDS) are associated with unusual susceptibility to infection by the pneumococcus. Children and adults with HIV infection are highly susceptible to pneumococcal infections.[26,160,6,89,150] Children with AIDS treated prophylactically with intravenous immune globulin have significantly fewer bacterial infections, especially pneumococcal infections.[270]

The presence of a normal spleen is important in containing pneumococcemia. In persons with anatomical or functional asplenia, there is a high risk of overwhelming sepsis. Congenital asplenia is often part of a complex of midline defects and is termed Ivemark's syndrome.[156] Individuals with this syndrome frequently die from severe cardiac disease in infancy. Of those who survive past 6 months of age, sepsis is a frequent occurrence and *S. pneumoniae* is most frequently the cause of sepsis.[278] Of those who have a splenectomy in later life, overwhelming pneumococcal sepsis is a significant threat. Posttraumatic splenectomy may be associated with a lower risk than elective surgical splenectomy because splenic rupture is often associated with splenosis (implantation of functioning spleen cells in the abdominal cavity). In the absence of splenosis, susceptibility to overwhelming pneumococcal sepsis is lifelong. The characteristic syndrome of overwhelming postsplenectomy infection is associated with *S. pneumoniae* in 50–90% of cases with a mortality rate of 50–70% despite treatment with appropriate antibiotics.[260]

The condition most clearly associated with acquired hypofunction of the spleen and hypersusceptibility to pneumococcal infection is sickle-cell anemia. In this disease the spleen is normal in the early months of life and then develops progressive autoinfarction due to stasis of sickled red cells. Finally, there is loss of splenic function even though the spleen may be anatomically present. This is the time of maximum susceptibility to life-threatening pneumococcal infection. The threat of pneumococcal sepsis and meningitis may be decreased by the use of prophylactic penicillin, or in those over 2 years of age, pneumococcal vaccine.[223,119]

The complement system has an important role in the pathogenesis of pneumococcal infections. Using animal models, it has been possible to demonstrate that opsonization of pneumococci, which is necessary for eradication of bacteremia, requires participation of the complement system.[41] Pneumococci can activate the terminal complement

components via the classical or alternative complement pathways. The alternative complement pathway can be activated by pneumococci and immunoglobulin that does not have to be specific for pneumococcal antigens. This pathway is responsible for "natural immunity" in non-immune individuals and activates opsonic C3b. Activation of the classical complement pathway is more efficient and occurs in immune individuals who have specific antipneumococcal antibody in the serum. It also involves activation of C3b. Hypersusceptibility to pneumococcal infection may be a consequence of dysfunction of either system. With congenital absence of any of the early components of the complement cascade, there is frequently recurrent infection, especially with pneumococci. In sickle-cell disease there is abnormally low function of the alternative complement system and this appears to be part of the susceptibility to overwhelming pneumococcal infections.[291]

7.2. Immunity

Type-specific anticapsular antibody appears on the fifth or sixth day of illness in untreated patients and promotes the ingestion of bacteria by leukocytes. The antibody appears to be protective and long-lasting and is specific for the pneumococcal capsular type. Recurrent systemic infection due to the same serotype is rare except in patients with impaired defenses or persistent foci of infection. However, the pneumococcus may persist in the upper-respiratory tract for days or weeks in the presence of humoral antibody.

Type-specific capsular antibodies also appear about 11 days after immunization, peak in 3–4 weeks, and persist at protective levels for at least 5 years.[238] Numerous studies have demonstrated that antibody production in response to pneumococcal polysaccharide vaccine is poor below the age of 2 years and is probably not effective in preventing infection in children of that age.[78,241] While type-specific immunity explains the success of the polysaccharide and conjugate vaccines, it does not explain the major decline in invasive pneumococcal disease that occurs around age 5[178] as young children could not have been exposed to the range of pneumococcal types by that age. Recent animal data suggest that antibody-independent mechanisms may explain immunity to pneumococcal carriage.[192]

8. Patterns of Host Response

8.1. Clinical Features

Pneumococcal infections in humans are manifested in various ways (Table 4). These range from the healthy carrier state or minor respiratory infection to pneumonia and meningitis, otitis media, conjunctivitis, and other focal purulent infections. Bacteremia may occur in association with manifestations ranging from simple pharyngitis and fever without a demonstrably localized lesion[198,265] to fulminating septicemia with purpura and adrenal hemorrhage (Waterhouse–Friderichsen syndrome), which may be rapidly lethal in the immunocompromised or asplenic patient.[279] Pneumococcal meningitis is most commonly a complication of skull fracture, sinusitis, mastoiditis, or pneumonia. Pneumococcal empyema of the pleura is a fairly common complication of pneumococcal pneumonia, which appears to be increasing in incidence, as described above, and infective endocarditis is generally a late complication.

Table 4. Clinical Spectrum of Pneumococcal Infections

Minor respiratory infections	Meningitis
Conjunctivitis	Focal infections
Otitis media	Febrile bacteremia
Sinusitis	Septicemia
Lobar pneumonia	Empyema of pleura
Bronchopneumonia	Endocarditis

Clinically, pneumococcal lobar pneumonia begins characteristically, most often after a few days of mild upper-respiratory symptoms, with a sudden severe chill or pleuritic pain or both. This is accompanied by a hacking cough, with production of small amounts of orange-, rust-, or prune-juice-colored sputum, and followed by fever and the appearance of physical and X-ray signs of consolidation of the lung(s). If the condition is untreated, the organism may invade the bloodstream (bacteremia), and the consolidation spreads to involve an entire lobe. It may spread to other parts of the lung, with a stormy course that ends in death or in recovery by rapid drop in fever and cessation of symptoms (crisis) or by slow resolution of fever, symptoms, and signs over several days (lysis).

In some areas of the world, such as sub-Saharan Africa, many of the patients presenting with pneumococcal infections are found to have concomitant HIV infection. In many of these patients the pneumococcal pneumonia is the presenting feature of the HIV infection, such that it has been recommended that patients presenting with invasive pneumococcal pneumonia should be offered counseling and testing for HIV infection. Investigators have studied the clinical presentation of bacteremic pneumococcal pneumonia, comparing HIV-seropositive and HIV-seronegative cases, and have noted some differences in presentation.[101] HIV-seropositive patients are younger, with a higher ratio of female patients. While some differences werenoted in the routine laboratory

parameters (lower admission white cell counts and serum albumin levels in the HIV-seropositive patients) and the microbiological data (more penicillin-resistant isolates and more of the so-called childhood serotypes/groups (6, 14, 19, 23) in the HIV-seropositive patients), there were no differences noted in the hospital course, complications, or outcome of the two patient groups.[101] However, recent analyses in which adjustments were made for age and severity of illness suggest that HIV-infected patients do, in fact, have a higher mortality, which is related, at least in part, to their level of immunocompromise, as indicated by their CD 4 cell count.[102]

9. Control and Prevention

9.1. Antibiotic Treatment

For many years the treatment of choice for pneumococcal infections remained penicillin to which the organism remained exquisitely sensitive. However, emerging penicillin and other antibiotic resistance has changed the prescribing recommendations and practices of many clinicians throughout the world. Much has been written about the impact of resistance to the various classes of antibiotics and the outcome of infections treated with these antibiotic classes alone. This topic has been reviewed elsewhere.[172,171,97] While it is interesting to note that there have been microbiologically documented failures of many of the different classes of antibiotics, including the cephalosporins, the macrolides, and even the fluoroquinolones, in cases infected with penicillin-nonsusceptible pneumococci, there have been no microbiologically documented failures of parenteral penicillin therapy in adequate dose. A prospective study of invasive pneumococcal infections involving 844 isolates from 22 countries on 6 continents documented no adverse effects of discordanttherapy on the outcome of these infections with the use of the high dose parenteral penicillin therapy or cefotaxime or ceftriaxone. The study did document a negative outcome in cases with cephalosporin-resistant isolates treated with cefuroxime at a dose of 750 mg TID.[294] Since the study of Yu and colleagues in 2003 at least four more recent studies appear to have confirmed the apparent lack of impact of antibiotic resistance on the outcome of most cases with antibiotic-resistant pneumococcal pneumonia, leading to the current increase in breakpoints for penicillin resistance in non – meningeal infections.[11,108,254,32]

More recently several studies investigating the impact of antibiotic therapy on outcome of bacteremic pneumococcal infections have suggested that the outcome of such infections is improved by the use of combination antibiotic therapy, most commonly that of a macrolide/azalide combined with standard beta-lactam therapy.[201,281,193,19,283,280] The reason for the benefit of combination therapy on outcome is uncertain and may well be multifactorial in origin. Suggested reasons include the presence of infections with the so-called "atypical pathogens" (*Chlamydia* spp., *Mycoplasma* spp., or *Legionella* spp.) requiring specific treatment with a macrolide/azalide, antimicrobial resistance of the isolates to one of the antimicrobial agents, the possibility of polymicrobial infections, antibiotic synergism, particularly occurring in immunocompromised patients and the non-antimicrobial, immunomodulatory, anti-inflammatory activity of the macrolide/azalide group of antibiotics.[280]

9.2. Prevention

Although controversy about the efficacy of active immunization with a polyvalent vaccine persists, it has been the mainstay for the prevention of invasive pneumococcal infections. However, investigators have also used passive immunization with specific immune intravenous immunoglobulin preparations in an attempt to decrease the mortality of critically ill patients with severe pneumococcal infections, without apparent benefit (Charles Feldman, personal communication).

9.3. Pneumococcal Polysaccharide Vaccine

Because of the extremely high incidence of serious pneumococcal infections among South African goldminers,[194] Wright and his co-workers in 1911[292] immunized miners with a crude whole-cell pneumococcal vaccine. Subsequently, a number of other investigators conducted clinical trials of the safety and efficacy of polysaccharide vaccines against pneumococci of various serotypes.[181,85,106] The validity of the results of many of these trials was questionable because of such methodological flaws as non-randomization, inadequacies in the clinical follow-up of subjects, and inadequacies in the bacteriological confirmation of the outcomes. Controlled trials of bivalent, trivalent, and quadrivalent polysaccharide vaccines that were conducted in the 1940s provided stronger evidence that vaccines were efficacious.[187,165] Two different hexavalent vaccines subsequently were commercially produced and marketed. At about the same time, antimicrobials that were effective against pneumococci became available and the outcomes of patients with pneumococcal infections improved substantially.

Interest in the vaccines rapidly diminished and they were eventually withdrawn from the market.

In 1964, Austrian and Gold[17] reported a mortality rate of 25% in adults with bacteremic pneumococcal pneumonia. Many of these patients died despite early treatment with appropriate antibiotics. Furthermore, most of the patients were either elderly or had a chronic illness which represented a population at increased risk of serious pneumococcal disease. This population could be targeted for immunization if an effective vaccine could be developed. Accordingly, Austrian and others worked together to develop a polyvalent vaccine.[18] The vaccine was tested with prospective, double-blind, randomized, controlled trials in young South African goldminers. This group of subjects was chosen because of the extraordinarily high incidence of pneumococcal disease they experienced, which enabled these trials to be conducted expeditiously and at a relatively low cost.[18]These well-designed trials produced conclusive evidence of the efficacy of these vaccines in this population (the estimates of protective efficacy ranged from 76 to 92%).[18,253]

Two large clinical trials were conducted to try to assess the vaccine's efficacy in populations at high risk of serious pneumococcal disease in the United States.[13] These trials were conducted among 13,600 ambulatory patients over 45 years of age at the Kaiser-Permanente Health Plan in San Francisco and among 1,300 subjects at a chronic-care facility in North Carolina. Despite the relatively large number of subjects, the results were inconclusive because of the low incidence of invasive pneumococcal infections and the consequent limited statistical power of these trials.[13,240] A small clinical trial conducted among patients with sickle-cell disease found excellent efficacy for these patients, but the study was flawed because the trial was neither randomized nor blinded.[4]

Despite these equivocal results, a 14-valent vaccine that contained 50 μg each of the polysaccharide antigen of 14 serotypes of pneumococci was licensed by the FDA in 1977. This vaccine was replaced in 1983 by one containing polysaccharide antigens of 23 capsular types (Table 3). The vaccine was recommended for use in persons over 2 years of age with a variety of chronic conditions that placed them at increased risk of serious pneumococcal infection.[54] These conditions included anatomical or functional asplenia and chronic pulmonary, cardiac, or renal diseases. The recommendations for the exact target population were rather vague, in part because of a lack of firm data on the magnitude of the increased risk of serious pneumococcal infections associated with various chronic conditions. The most recent recommendations from the Immunization Practices Advisory Committee (ACIP) of the CDC are as follows:[56,57]

Adults

1. Immunocompetent adults who are at increased risk of pneumococcal disease or its complications because of chronic illnesses (e.g., cardiovascular disease, pulmonary disease, diabetes mellitus, alcoholism, cirrhosis, or cerebrospinal fluid leaks) or who are ≥ 65 years old.
2. Immunocompromised adults at increased risk of pneumococcal disease or its complications (e.g., persons with splenic dysfunction or anatomic asplenia, Hodgkin's disease, lymphoma, multiple myeloma, chronic renal failure, nephrotic syndrome, or conditions such as organ transplantation associated with immunosuppression).
3. Adults with asymptomatic or symptomatic HIV infection.

Children

1. Children ≥ 2 years old with chronic illnesses sporadically associated with increased risk of pneumococcal disease or its complications [e.g., anatomic or functional asplenia (including sickle cell disease), nephrotic syndrome, cerebrospinal fluid leaks, and conditions associated with immunosuppression].
2. Children ≥ 2 years old with asymptomatic or symptomatic HIV infection.
3. The currently available 23-valent vaccine is *not* indicated for patients having only recurrent upper-respiratory-tract disease, including otitis media and sinusitis.

Special Groups

1. Persons living in special environments or social settings with an identified increased risk of pneumococcal disease or its complications (e.g., certain Native American populations).

Adverse Reactions

1. Approximately 50% of persons given pneumococcal vaccine develop mild side effects, such as erythema and pain at the injection site. Fever, myalgia, and severe local reactions have been reported in <1% of those vaccinated. Severe systemic reactions, such as anaphylaxis, rarely have been reported.

Precautions

1. The safety of pneumococcal vaccine for pregnant women has not been evaluated. Ideally, women at high risk of pneumococcal disease should be vaccinated before pregnancy.

Timing of Vaccination

1. When elective splenectomy is being considered, pneumococcal vaccine should be given at least 2 weeks before the operation, if possible. Similarly, for planning cancer chemotherapy or immunosuppressive therapy, as in patients who undergo organ transplantation, the interval between vaccination and initiation of chemotherapy or immunosuppression should also be at least 2 weeks.

Revaccination

1. In one study, local reactions after revaccination in adults were more severe than after initial vaccination when the interval between vaccinations was 13 months. Reports of revaccination after longer intervals in children and adults, including a large group of elderly

persons revaccinated at least 4 years after primary vaccination, suggest a similar incidence of such reactions after primary vaccination and revaccination.

2. Without more information, persons who received the 14-valent pneumococcal vaccine should not be routinely vaccinated with the 23-valent vaccine, as increased coverage is modest and duration of protection is not well defined. However, revaccination with the 23-valent vaccine should be strongly considered for persons who received the 14-valent vaccine if they are at highest risk of fatal pneumococcal infection (e.g., asplenic patients).
3. Revaccination should also be considered for adults at highest risk who received the 23-valent vaccine 6 years before and for those shown to have rapid decline in pneumococcal antibody levels (e.g., patients with nephrotic syndrome, asplenia, or sickle-cell anemia who would be ≤10 years old at revaccination).

New recommendations from the Advisory Committee on Immunization Practices for the prevention of pneumococcal disease were issued in April, 1997. The major change is that revaccination with polyvalent pneumococcal polysaccharide vaccine is recommended for patients 65 years of age or older who received the vaccine five or more years earlier and were <65 years of age when they last received the vaccine. Reimmunization also is recommended both for persons with either functional or anatomic asplenia and for immunocompromised persons if 5 or more years have elapsed since the last dose (for persons <11 years of age, if 3 or more years have elapsed since the last dose).

Strategies for Vaccine Delivery

1. Recommendations for pneumococcal vaccination have been made by the ACIP, the American Academy of Pediatrics, the American College of Physicians, and the American Academy of Family Physicians. Recent analysis indicates that pneumococcal vaccination of elderly persons is cost-effective. The vaccine is targeted for approximately 27 million persons aged ≥ 65 years and 21 million persons ages <65 years with high-risk conditions. Despite Medicare reimbursement for costs of the vaccine and its administration, which began in 1981, annual use of pneumococcal vaccine has not increased above levels observed in earlier years. In 1985, <10% of the 48 million persons considered to be at increased risk of serious pneumococcal infection were estimated to have ever received pneumococcal vaccine.
2. Opportunities to vaccinate high-risk persons are missed both at time of hospital discharge and during visits to clinicians' offices. Two thirds or more of patients with serious pneumococcal disease had been hospitalized at least once within 5 years before their pneumococcal illness, yet few had received pneumococcal vaccine. More effective programs for vaccine delivery are needed, including offering pneumococcal vaccine in hospitals (at the time of discharge), clinicians' offices, nursing homes, and other chronic-care facilities. Many patients who receive pneumococcal vaccine should also be immunized with influenza vaccine.

The recommendation for use in children 2–5 years of age at increased risk of invasive pneumococcal infection has been modified[58] to include conjugate vaccine as follows: two doses of conjugate vaccine ≥ 2 months apart followed by 23-valent vaccine ≥ 2 months later. Children who have already received polysaccharide aged 2–5 years should receive two doses of conjugate as above, ≥ 2 months after the polysaccharide. Because of potential concerns about the induction of tolerance, polysaccharide vaccines should follow, not precede conjugate immunizations.

Based on systematic surveillance of the serotypes of pneumococci that caused serious invasive disease, the vaccine was formulated to include serotypes that were responsible for approximately 80% of the cases of systemic pneumococcal infections in the United States.[39,40,38] However, soon after the vaccine was licensed and distributed, reports of clinical failures of the vaccine began to appear.[1,126] Furthermore, studies suggested that some high-risk patients had poor antibody responses to the vaccine.[175,5,125] In addition, surveillance data from the CDC suggested that vaccine efficacy was poor for many high-risk patients.[39,37] Thus, there was considerable uncertainty about the vaccine because it was shown to be effective in a very select population (young goldminers), but there were serious questions about its efficacy for the population in the United States that was at increased risk of serious pneumococcal infections. However, because of the low incidence of bacteremic pneumococcal infections in developed countries, even in high-risk patients, there are formidable logistical and financial obstacles to conducting a randomized clinical trial in the United States.[60] Furthermore, because the vaccine is licensed (and presumably is efficacious), it may be unethical to allocate high-risk patients randomly to receive placebo, as would be necessary in a randomized trial.

Alternatives to randomized clinical trials to assess the vaccine's efficacy were necessary.[60] Shapiro and Clemens[245] conducted a case–control study that found the vaccine's efficacy to be 67% (95% confidence interval: 13–87%) in high-risk patients. Although there were too few subjects to assess the vaccine's efficacy accurately in immunocompromised patients, its efficacy in high-risk patients with chronic conditions such as diabetes mellitus or chronic pulmonary, cardiac, or renal disease was 77% (95% confidence interval: 27–93%). Bolan and colleagues[31] from the CDC extended their estimates of the vaccine's efficacy based on their surveillance data of reports of serotypes of pneumococci that caused bacteremic disease from 1978 to 1984. They found the vaccine's efficacy against bacteremic disease to be 64% (95% confidence interval: 47–76%). Based on these results, experts have concluded that the vaccine is cost-effective and that it is underutilized.[56,222,16,174,249]

Despite the serious obstacles to such a study, Simberkoff and colleagues[246] conducted a randomized clinical trial of the protective efficacy of the 14-valent vaccine at several different Veterans Administration medical centers. Although they were unable to demonstrate that the vaccine was efficacious, there were a number of serious flaws in their methodology that compromise the validity of their conclusions.[243]

Many of the events that the investigators counted as episodes of pneumococcal infection were really of uncertain cause since their definition of pneumococcal infection included patients with a cough and isolation of pneumococci from their sputa (even in the absence of an abnormal chest X-ray). Because it is known that immunization with pneumococcal vaccine will not affect colonization of the respiratory tract with pneumococci, the definitions of pneumococcal infection used in this study limit its usefulness. By the investigators' own criteria, there were only two subjects with proven (bacteremic) pneumococcal infection. As a result, the statistical power of the study to assess the vaccine's efficacy against proved pneumococcal infections was extraordinarily poor (only 6%).

Despite the recommendations of official bodies such as the ACIP[56] and the American College of Physicians[143] that pneumococcal vaccine be administered to high-risk patients, physicians have been slow to implement these recommendations. Studies have indicated that fewer than a quarter of the eligible patients have received the vaccine.[245,90] Consequently, one of the major issues in maximizing the full potential benefit of this vaccine is to find a strategy to increase its utilization among high-risk patients. Fedson[90] and others have found that a large majority of the patients who develop pneumococcal bacteremia had been hospitalized in the preceding several years. Consequently, he suggests a strategy of immunizing with pneumococcal vaccine hospitalized patients who have indications for the vaccine.[90]

The most definitive postlicensure study of the vaccine's protective efficacy is a case–control study by Shapiro et al.,[244] conducted from 1984 to 1990, of 1,054 adults with systemic (usually bacteremic) pneumococcal infection who had one or more indications for pneumococcal vaccine and 1,054 matched controls. The case subjects were stratified into a very high risk, immunocompromised group (18% of the cases) and an immunocompetent group (82% of the cases). The estimate of the vaccine's aggregate protective efficacy (against serotypes in the vaccine) was 61% (95% confidence interval: 47–72%; $p < 0.00001$) among the immunocompetent patients but was only 21% (95% confidence interval: 55–60%; $p = 0.48$) for the immunocompromised group. Although this was an observational study, the findings were robust and did not change after statistical adjustment for potential confounders. In addition, using the same methods, the investigators found that the vaccine was not efficacious in preventing infections caused by serotypes not included in the vaccine and that there was no statistically significant difference in the proportion of cases and controls who had received influenza vaccine. These observations help assure that the findings were not substantially affected by bias and that the conclusions of the investigators were valid.

A report from the CDC in which the vaccine's protective efficacy was assessed based on an indirect cohort method had results similar to those of Shapiro and co-workers.[244] In that study (based on isolates of pneumococci from normally sterile sites that were submitted to the CDC from 1978 to 1992) the investigators found that the vaccine was efficacious in immunocompetent persons with indications for the vaccine (estimates of efficacy ranged from 65 to 75%, depending on the underlying disease), but that it was not efficacious (although the confidence intervals around the estimates were wide) for severely immunocompromised patients such as those with sickle-cell disease, lymphoma, or multiple myeloma.[50]

An area of particular controversy that has not been resolved is whether there is a significant decline in the efficacy of the vaccine over time. Although there does seem to be some decline, the magnitude of the decline (at least over 5–8 years) is relatively modest and some of this decline may be attributable to increased cumulative risk over time of exposure to serotypes of pneumococci in the vaccine. It is not clear that revaccination will reverse this effect. Nevertheless, the risk of adverse side effects from revaccination is small and is related to how soon after the first vaccination it occurs (if >1 year after the first vaccination, the risk of severe adverse reactions is extremely small). Consequently, revaccination is recommended for those at particularly high risk of serious pneumococcal infections.

The vaccine has been shown in case–control studies to be protective in HIV-infected patients in the US – most of these patients, however, are receiving HAART. The risk of pneumococcal disease in the HAART era remains elevated[133,144] and the recommendation in favor of the vaccine seems reasonable in this population. In populations of HIV-infected people without access to HAART, the vaccine has been shown not to be effective[117] and may in fact be harmful, presumably on the basis of committing memory B cells to the vaccine in individuals unable to mount an immune response or to replenish their memory B cells. The vaccine has not been shown to reduce non-bacteremic pneumonia in randomized trials in the elderly.[157]

The type-specific pneumococcal polysaccharide appears to be a largely T-cell-independent antigen. Booster (anamnestic) responses to repeated exposure to the polysaccharide antigen are not observed.[33] Although the attack rate of invasive pneumococcal infection is very high in young children, most of the serious infections occur in children under 2 years of age. Unfortunately, children under 2 years of age have a poor immunologic response to T-cell-independent antigens such as those in pneumococcal vaccine.

Consequently, universal immunization of children with pneumococcal polysaccharide vaccine was not recommended, since most cases of serious disease occur among young children who are unlikely to respond to the vaccine.[122] The vaccine also has not been effective in preventing otitis media in young children.[122] Pneumococcal vaccine is indicated to booster conjugate vaccine for children 2 years of age or older with chronic conditions that place them at increased risk of serious pneumococcal infections.[46,122]

Although there continues to be some controversy about the protective efficacy of polyvalent pneumococcal polysaccharide vaccine for adults, there is little doubt that it is not efficacious in most children <2 years of age – the group at highest risk of serious pneumococcal infections.

9.4. Pneumococcal Conjugate Vaccines

In the year 2000, the first 7-valent pneumococcal conjugate vaccine was licensed. The 7-valent vaccine (Table 3) contains serotypes 4, 6B, 9 V, 14, 18C, 19F, and 23F (a 9-valent version includes additionally types 1 and 5; a 10-valent version also contains serotype 7, which is a relatively common cause of otitis media; a 13-valent version includes also serotypes 6A, 7F, and 19A, the first and last of which are important antibiotic-resistant types). The serotypes in the 7-valent vaccines are responsible for 80–85% of invasive pneumococcal infections (and for about 75% of the cases of pneumococcal otitis media) in the United States. Addition of other serotypes, such as serotypes 1 and 5, will be important to increase the proportion of serious infections that might be prevented by the vaccine in developing countries.[21] These vaccines have been shown to be immunogenic in infants and primes them for anamnestic antibody responses to a booster dose of either the conjugate or the plain polysaccharide vaccine.[166,155]

Pneumococcal 7-valent vaccine conjugated to diphtheria protein CRM_{197} has been shown in large double-blind randomized trials in California[28] and the Navajo[208] to prevent >85% of invasive disease due to vaccine serotypes. Similar levels of efficacy have been found using the same vaccine in a 9-valent formulation including serotypes 1 and 5 in Africa.[173,71] Vaccine efficacy has also been established in one of these studies among HIV-infected infants with protection against invasive disease of 65%.[173] In contrast to the lack of evidence for protection based on randomized trials using 23-valent vaccine in the elderly, clinical trials of the conjugate vaccines do show prevention of pneumonia in young children.[29,173,71] Conjugate vaccines can thus be used to define the vaccine-preventable fraction of pneumonia.[190] These studies have shown that a significant fraction of vaccine-preventable pneumonia in children is not associated with consolidation on X-ray and that adjunctive tests such as a raised CRP (>40 mg/dl) may be a useful predictor of a pneumococcal etiology.[189] Further, the conjugate vaccine as a probe has found that 45% of influenza-associated pneumonias in African children may be pneumococcal.[188] These data suggest a major role for conjugate vaccine in preventing influenza-associated morbidity due to pneumococcal superinfection. Much of the pneumonia associated with other respiratory viruses such as RSV, parainfluenza viruses, and human metapneumovirus may also be prevented in children who have received pneumococcal conjugate vaccine.[188]

The recommendations for pneumococcal conjugate vaccines according to the ACIP[58] are

Children for Whom PCV7 Is Recommended

Children Aged≤ 23 Months

All children aged ≤ 23 months should be vaccinated with PCV7 (Strength of evidence: children aged 2–6 months, A; children aged 7–23 months, B)

Vaccination Schedule. Infants receiving their first dose at age ≤ 6 months should receive three doses of PCV7 at intervals of approximately 2 months, followed by a fourth dose at age 12–15 months. Newborns should begin the schedule at age 2 months, although PCV7 can be administered as young as age 6 weeks. Prematurely born infants (i.e., <37 weeks gestation) should receive PCV7 at the recommended chronologic age concurrent with other routine vaccinations. For infants with prolonged nursery stays, initiation of vaccination should begin during discharge planning. Children aged ≥7 months not previously vaccinated should also be vaccinated according to the recommended schedule. The proposed vaccination schedule is the same for all children aged ≤23 months, regardless of the presence of underlying medical conditions (e.g., children with HIV infection, SCD or other asplenia, chronic disease, or who are otherwise immunocompromised). Interruption of the vaccination schedule does not require reinstitution of the entire series or the addition of extra doses.

Children Aged 24–59 Months Who Are at High Risk for Pneumococcal Infection

Children aged 24–59 months should receive PCV7 vaccination if they are at high risk for pneumococcal infection caused by an underlying medical condition. This recommendation applies to the following groups:

- children with SCD and other sickle cell hemoglobinopathies, including hemoglobin SS, hemoglobin S-C, or hemoglobin S-β-thalassemia, or children who are functionally or anatomically asplenic;
- children with HIV infection;
- children who have chronic disease, including chronic cardiac and pulmonary disease (excluding asthma), diabetes mellitus, or CSF leak; and
- children with immunocompromising conditions, including a) malignancies (e.g., leukemia, lymphoma, Hodgkin's disease); b) chronic renal failure or nephrotic syndrome; c) those children receiving immunosuppressive chemotherapy, including long-

term systemic corticosteroids; and d) those children who have received a solid organ transplant.

SCD and HIV (Strength of evidence: B). Chronic disease or other (Strength of evidence: C).

Vaccination Schedule. For children aged 24–59 months with underlying medical conditions ACIP recommends two doses of PCV7, administered 2 months apart, followed by one dose of PPV23 administered ≥2 months after the second dose of PCV7. Penicillin prophylaxis should be continued for children with SCD to age ≥5 years, regardless of vaccination with PCV7.

Other Children Who Might Benefit from Vaccination with PCV7

ACIP recommends that health-care providers consider PCV7 vaccination for all other children aged 24–59 months, with priority given to the following populations:

- children aged 24–35 months;
- children of Alaska Native or American Indian descent;
- children of African-American descent;
- children who attend group day care centers;

(Strength of Evidence: B).

If pneumococcal vaccine is to be used among healthy children aged 24–59 months, ACIP recommends that PCV7 be used.

Vaccination Schedules. ACIP recommends that one dose of PCV7 be considered for Alaska Native and American Indian children aged 24–59 months. Vaccination program personnel and other health-care providers might consider whether Alaska Native and American Indian children aged 24–59 months would benefit by the additional coverage provided by the 23-valent polysaccharide vaccine. ACIP recommends that physicians consider administering one dose of PCV7 to their African-American pediatric patients aged 24–59 months because of their increased risk for pneumococcal infection. No additional vaccination with PPV23 is recommended (Strength of evidence: B). Additionally, because of increased risk for invasive pneumococcal disease, colonization with antibiotic-resistant pneumococcal strains, and AOM, health-care providers should consider administering one dose of PCV7 to previously unvaccinated children aged 24–59 months who attend group day care centers.

Children Aged ≥5 Years and Adults Who Are At High Risk for Pneumococcal Infection

Administering PCV7 to older children with high-risk conditions is not contraindicated. Current data do not support a recommendation to replace PPV23 with PCV7 among older children and adults.

Recommendations for Use of PCV7 Among Children Previously Vaccinated with PPV23

Children aged 24–59 months who are at high risk for pneumococcal disease and who have already received PPV23 (i.e., children with SCD, HIV infection, or who have other immunocompromising illnesses or chronic diseases) could benefit from the immunologic priming and T-cell-dependent immune system response induced by PCV7. Thus, among children in these groups at high risk, sequential use of the two pneumococcal vaccines can provide additional protection. Health-care providers should vaccinate children aged 24–59 months at high risk who have not previously received PCV7 but who have already received PPV23 with two doses of PCV7 administered ≥2 months apart. Vaccination with PCV7 should be initiated ≥2 months after vaccination with PPV23. Providers should be aware that minimal safety data are available regarding this vaccine sequence.

Recommendations for Use of PPV23 Among Children Previously Vaccinated with PCV7

Administration of PCV7 Followed by PPV23 Among Children at High Risk for Pneumococcal Disease

Children who have completed the PCV7 vaccination series before age 2 years and who are among risk groups for which PPV23 is already recommended should receive one dose of PPV23 at age 2 years (≥2 months after the last dose of PCV7). These groups at high risk include children with SCD, children with functional or anatomic asplenia, children who are HIV infected, and children who have immunocompromising or chronic diseases. Although data regarding safety of PPV23 administered after PCV7 are limited, the opportunity to provide additional serotype coverage among these children at very high risk justifies use of the vaccines sequentially. For children of Alaska Native or American Indian descent, addition of PPV23 after PCV7 can be considered.

Pneumococcal conjugate vaccines not only prevent invasive disease and pneumonia, but have also been shown to prevent 50–60% of vaccine-serotype otitis media.[86,167] Serotype replacement, however, is a significant problem for otitis media prevention, such that the overall protection against clinical otitis media is limited.[28,86] It is possible that a formulation of the conjugate with protein D of *H. influenzae* may result in less replacement, and due to its impact also on nontypeable haemophilus, may prevent a greater fraction of otitis media.[227] Direct comparison of the efficacy of the two vaccines (CRM_{197} versus *Haemophilus* protein D conjugates) is complicated by a more stringent definition of otitis media in the protein D trial.

These conjugate vaccines also reduce vaccine type carriage,[170,227] although there is clear evidence for serotype replacement among recipients of the CRM_{197}-based conjugates.[170] The impact on colonization appears to be prevention of acquisition of new strains rather than eradication of existing carriage[195] and may be mediated by very high values of circulating IgG that may diffuse onto mucosal surfaces.[73] The major impact of conjugate vaccine on serotype-specific acquisition of carriage is that transmission of pneumococci is interrupted in families[130] and communities.[147] In the United States there has been a dramatic reduction of >65% in invasive disease due to the conjugate vaccine serotypes amongst the elderly, since the introduction of conjugate vaccine in children.[288] Decreases of a similar magnitude have been noted among HIV-infected adults although there is evidence of more replacement disease among HIV-infected people, particularly women.[116]

Finally the conjugate vaccine has been shown to protect children from antibiotic-resistant invasive disease[173]

and from carriage of resistant strains.[195,74] This impact on resistance has also been translated into herd immunity and there have been reductions in antibiotic-resistant bacteremias in the United States following conjugate vaccine introduction.[27,263,256] The reduction in resistance has been less in upper-respiratory tract specimens as a result of replacement and continuing selection of resistance among non-vaccine types.[215]

10. Unresolved Problems

The detailed studies of the pneumococcus have been the basis of modern molecular biology and immunochemistry. Probably more is known about the biology of the pneumococcus than about that of any other bacterium. However, the exact mechanism(s) whereby this organism is able to multiply in animal and human tissue and produce its more or less unique type of inflammation in the lung is not fully known. Some progress has been made in the elucidation of the function of various chemical and morphological constituents of the pneumococcus other than the capsular polysaccharide.[113,270] Although many of the defects in cellular and humoral immunity that predispose to pneumococcal infections have been revealed, there are still others that need to be elucidated. Also, the exact mechanism whereby viral infection and chemical irritants predispose local pulmonary tissues to pneumococcal disease needs further elucidation. The reasons for the predominance of infection in males need to be clarified, as does the increased susceptibility of black people, apart from environmental factors. The basis for virulence of pneumococci needs further study. Finally, while pneumococcal vaccines are currently in use, the extent of their global use in target populations is too low, and the challenge remains to get conjugate or pure protein-based vaccines to the millions of at-risk children and adults currently without access to existing vaccines.

ACKNOWLEDGMENTS

The authors wish to thank Rachel Patzer for her many hours spent bringing the references in this chapter into the electronic age.

CHAPTER 30

Q fever

Thomas J. Marrie

1. Introduction

Q fever is the illness in man due to infection with the microorganism *Coxiella burnetii*. It is a zoonosis and its epidemiology is closely linked to the animal reservoirs of the causative microorganism, *C. burnetii*. Important elements of the epidemiology of this infection can be learned from the history of its discovery and early investigations; a consideration of the macro-epidemiology at the level of a country; knowledge about the microorganism and the routes of transmission; the epidemiology of Coxiellosis in animals; and finally exploration of the epidemiology at a local level and the lessons learned from outbreaks.

2. Historical Aspects

Dr. E. H. Derrick, a pathologist and Director of the Laboratory of Microbiology and Pathology at the Queensland Health Department, Brisbane, Australia, was contacted by Sir Raphael Cilento, Director General of Health and Medical Services for Queensland in August 1935.[1] Cilento asked Derrick to investigate an outbreak of an undiagnosed febrile illness among workers at the Cannon Hill abattoir in Brisbane.[1]

Derrick first carefully described the clinical illness. He noted that it lasted 7–24 days and was characterized by fever, headache, malaise, anorexia and myalgia. Blood cultures were negative and serum samples from the affected individuals had no antibodies to influenza, typhus, leptospirosis, typhoid and paratyphoid. He named the illness Q (for query) fever.[2]

Thomas J. Marrie • Walter C. Mackenzie Health Sciences Center, Edmonton, Alberta T6G 2B7, Canada

Derrick proceeded to investigate the cause of the outbreak by inoculating blood and/or urine from his febrile patients into guinea pigs. The guinea pigs became febrile and when emulsified tissue from these animals was injected into uninfected guinea pigs they too developed fever. However, despite considerable effort Derrick was unable to isolate a microorganism from the guinea pigs. In October 1936 he decided to enlist the aid of Frank MacFarlane Burnet, a virologist (and later a Nobel laureate), who was working at the Walter and Eliza Hall Institute in Melbourne. He sent a saline emulsion of infected guinea pig liver to Burnet. Burnet and his research associate Mavis Freeman found oval areas about the size of a nucleus in sections of spleen from a mouse that had been inoculated with Derrick's specimen. When these smears were stained by Castaneda's method "bodies which appeared to be of rickettsial nature were found sometimes in enormous numbers".[3]

In the spring of 1935 investigators at the Rocky Mountain Laboratory in Hamilton, Montana were trying to find the etiological agent of Rocky Mountain Spotted Fever. As part of this *Dermacentor andersonii* ticks, collected from the Nine Mile Creek area, were brought to Gordon Davis, one of the investigators at the Laboratory.[2] Davis was able to isolate an organism from these ticks.

McFarlane-Burnet sent his "organism" to NIH and by 1938 it was apparent that the tick agent and the Q fever agent were identical. Herald Rea Cox, a Rocky Mountain Laboratory Scientist, and Davis after a great deal of work were able to grow the Nine Mile Agent in embryonated eggs.

Rolla Dyer (Director of the National Institutes of Health from 1942 to 1950) heard about this discovery and visited the Rocky Mountain Lab to review the data. He was convinced that these workers had isolated a microorganism. A few days later on the train on the way back to Washington he developed fever and a severe retro-orbital headache. The

A.S. Evans, P.S. Brachman (eds.), *Bacterial Infections of Humans*, DOI 10.1007/978-0-387-09843-2_30,
© Springer Science+Business Media, LLC 2009

Nine Mile/Q fever agent was isolated from his blood.[1] This represents the first example of laboratory-acquired Q fever.

Over the years there have been a series of names for this agent – initially *Rickettsia diaporica* (diaporica, Greek for having the property or ability to pass through – describing the filterability of this agent); then *R. burnetii* was proposed and later it was elevated to a subgenus, *Coxiella*.[1] The agent is now known as *C. burnetii* in honor of Cox and Burnet who both died in 1986.

3. Methodology

3.1. Sources of Data

The data sources used for this chapter included an extensive personal collection of papers and books on Q fever and a Medline search to obtain the latest references on Q fever. In addition unpublished observations made by the author were also included. Surveillance data from the US Centres of Disease Control and Prevention were also used.

3.2. Surveys

Most of the surveys that relate to Q fever are seroepidemiological ones. Data from selected surveys are incorporated throughout the manuscript.

3.3. Laboratory Diagnosis

Coxiella burnetii is highly infectious and only category IV laboratories are licensed to isolate it. However, it can be readily isolated from clinical specimens using tissue culture.

Most clinical laboratories use serology as their diagnostic method of choice for this infection. The reference method is the indirect immunofluorescence test. In this method cells from phase I and phase II microorganisms are used. A titre of $\geq$1:8 is considered positive, although in some countries a higher cutoff is used. (The cut off used depends on the antigen and the population being studied). A fourfold rise between acute and convalescent serum specimens is diagnostic of acute Q fever. In acute Q fever the phase II titer is always higher than the phase I titer. In contrast in chronic Q fever, the phase I titer is equal to or higher than the phase II titer. Very high titers such as $\geq$1:16,384 are seen in chronic Q fever. Other serological methods include the complement fixation and enzyme-linked immunosorbent assay. Molecular diagnosis is being used more frequently. Polymerase chain reaction using a variety of primers can be used to amply *C. burnetii* DNA from clinical specimens. However, such a test is not readily available in most diagnostic laboratories.

4. Biological Characteristics of the Organism

In order to understand the epidemiology of Q fever it is necessary to understand some of the unique aspects of the causative organism. *C. burnetii*, an obligate intracellular microorganism, is a pleomorphic coccobacillus with a gram-negative cell wall[4]; it measures 0.2 $\times$ 0.7 μm and has a developmental cycle in which there is a large and small cell variant.[5] The acid pH of the phagolysosome is necessary for development of *C. burnetii,* since the low pH activates its metabolic enzymes.[6] Following maturation of the large cell variant sporogenesis begins.[7] Spore-like formation explains why *C. burnetii* is so successful as a pathogen. It can survive for 7–10 months on walls at 15–20°C, for more than 1 month on meat in cold storage and for more than 40 months in skim milk at room temperature.[7,8]

Coxiella burnetii undergoes phase variation, which is akin to the smooth to rough transition of the lipopolysaccharide of gram-negative bacteria.[9] In nature and in laboratory animals it exists in phase I state in which organisms react with late (45 days) convalescent guinea pigs sera and only slightly with early (21 days) sera.[9] Studies by Hackstadt[10] and Lukacova et al.[11] have shown that in experimentally infected animals the first antibody production is to *C. burnetii* protein – phase II antigen – and later antibody is produced to *C. burnetii* LPS – phase I antigen.

Understanding phase variation is of more than academic interest in that in man high antibody titers ($\geq$1:800), using an indirect immunofluoresence technique, to phase I antigen are suggestive of chronic Q fever, while phase II antibodies predominate in acute Q fever.[12] There is no morphological difference between phase I and phase II cells although they do differ in the sugar composition of their lipopolysaccarides,[13] their buoyant density in cesium chloride and their affinity for basic dyes. The LPS of *C. burnetii* is non-toxic to chick embryos at doses of $>$80 μg/embryo in contrast to *Salmonella typhimurium* LPS which is toxic in nanogram amounts.[11]

Coxiella burnetii is able to survive in the phagolysosome because it produces the enzyme superoxide dismutase which protects it from host-generated superoxide anion and hydrogen peroxide.[14] In common with *Legionella* spp and *Leishmania* spp *C. burnetii* can inhibit the respiratory burst of phagocytosing neutrophils[15] by producing acid phosphatase.[16]

On the basis of 16s rRNA sequence similarities, *C. burnetii* has been placed in the gamma subdivision of proteobacteria with a distant relationship to *Legionella* and *Wolbachia persica*.[17,18]

The 1,995,275 base pair genome of *C. burnetii* phase I, Nine Mile strain, was recently sequenced.[19] It possesses 29 insertion sequence elements and 83 pseudogenes. Because

C. burnetii can persist in the external environment the absence of pathways for synthesis of storage compounds such as glycogen, trehalose or polyhydroxybutyrate was unexpected.[19]

5. Descriptive Epidemiology

5.1. Epidemiology of Q Fever in Selected Countries

5.1.1. United States. Q fever was not a notifiable disease in the United States until 1999, when, because of concerns about its potential as a biological warfare agent, it was added to the national list of notifiable diseases.[20] In two papers McQusiton et al.[20,21] reviewed the epidemiology of Q fever in the United States from 1948 to present. Between 1948 and 1977 a total of 1,168 cases were reported to the Centers for Disease Control and Prevention, a mean of 58.4 cases per year. They also noted that from 1978 to 1986 there was a decline in the number of reported cases to 28.5 per year. Most of the cases (67%) in this early period originated from California.[21] Careful studies of the epidemiology of Q fever in California led to the conclusions that Q fever was associated with exposure to sheep and goats.[22–26] During the course of these studies *C. burnetii* was recovered from the air of premises having infected goats,[23] from raw milk[24] and from the placentas of infected cows.[25]

During the period 1946–1950 outbreaks of Q fever were observed at meat packing plants in Texas and Chicago.[27–32] During the investigation of these outbreaks Shepard implicated aerosols as the route of transmission of Q fever.[32]

In her most recent paper McQusiton[20] reported that from 1978 to 1999 there were 436 cases of Q fever in the United States, an average of 26 cases per year with a range of 6–41 cases. From 2000 to 2004 there were 255 cases from 37 states, an average of 51 per year, range 18–73 cases. These investigators noted a seasonal effect, with 39% of the cases reported from April through June. Seventy-seven percent were male; the mean age was 50.5 years; median 51 years; 92% were white; 6% black; 2% Asian. The racial distribution of the Q fever cases was proportionally similar to that of the US population. The age distribution of the Q fever cases differed from that of the US population with the Q fever cases increasing with increasing age and peaking in the 50–59 year age group. The overall rate for the United States was 0.28 cases per million population per year. The highest rate was in Wyoming. No cases were reported from Alabama, Alaska, Arkansas, Connecticut and Hawaii. Q fever is not reportable in the following states: Delaware, Iowa, Vermont and West Virginia. Hence no data were given for these states.

In a recent study Kim et al.[33] tested 316 bulk milk tanks throughout the United States using PCR to test for the presence of *C. burnetii* DNA. The milk was collected from January 2001 through December 2002 and 94.3% of the samples were positive.

Karakousis et al.[34] reported a case of chronic Q fever and reviewed all the published cases of chronic Q fever from the United States. They could only find seven such cases, likely a gross underestimate, from 1976 to 2004.

McQusiton[21] noted that sheep and goats in the United States have a higher seroprevalence for *C. burnetii* than cattle. While only one study has been published for each of these animals the seropositivity rate among tested dogs was 53%, cats 8% and horses 25.6%.[21] McQuiston also noted an extensive wildlife reservoir for this organism in the United States.[21] Various studies have shown varying degrees of seropositivity for coyotes, grey foxes, skunks, raccoons, rabbits, deer, mice, bears, birds and opossums.

5.1.2. Germany. Hellenbrand, Breuer and Peterson reviewed the epidemiology of Q fever in Germany from 1947 to 1999.[35] In West Germany, Q fever has been a notifiable disease since 1962 and in East Germany since 1979.[35] Q fever peaked in West Germany in 1964 at 450 cases. The average incidence from 1979 to 1999 was 1.1 cases per million persons per year. The rate was highest in southern German states with the highest rate in Baden–Wurttemberg at 4.1 per million per year. They noted that 40 outbreaks of Q fever in humans had been reported. Sheep were implicated in 24, cattle in 6 and there were two laboratory outbreaks. The seasonality changed over the past decade with a marked decrease in winter outbreaks and an increase in summer outbreaks. They also noted that in contrast to earlier community outbreaks which were almost exclusively rural; recent outbreaks have frequently involved people living in urban areas.[35] The location of recent outbreaks suggests that urbanization of rural areas may be contributing to the increase in Q fever.

In Germany, State Veterinarians are required to report biannually the number of herds in which one or more animals have laboratory-confirmed Q fever. The average number of herds positive was 71 between 1971 and 1979, 328 from 1980 to 1989 and 303 from 1990 to 1998. In 1998, 7.8% of 21,191 cattle tested were positive, while 1.3% of 1,346 sheep and 2.5% of 278 goats were positive.[35]

5.1.3. Australia – Including Post Q Fever Fatigue Syndrome (QFFS). In this, the country where it was first recognized, Q fever continues to thrive. In Australia, 6,479cases of Q fever were diagnosed from 1960 to 1986.[36] From 1991 to July 2006 there were 8368 cases, with a range of 354–869 cases per year.[37] The rate of Q fever in Australia is about 30 per million per year.[38] Males are predominantly

involved, with a male:female ratio of 5.3:1.[39] One of the unique risk factors for Q fever in Australia is kangaroo hunting.[40] Another aspect of Q fever epidemiology that is unique to Australia is the widespread use of a *C. burnetii* vaccine in animals.[41] A large outbreak of Q fever in an abattoir near Adelaide that previously processed bacon pigs but added feral goats to their program prompted the vaccine program. The Henzerling strain of *C. burnetii* prepared according to the Ormsbee protocol (Q vax) was chosen. Potential vaccines were screened for antibodies to *C. burnetii* and those who were negative were skin tested intra-dermally for cell-mediated immunity. If the skin test was negative the vaccine was administered. It took some time for the vaccine to gain acceptance, but by 1993, according to Marmion, good progress had been made and by 2004 most large abattoirs in states other than Tasmania (which has fewer cases) had vaccine programs. From 1993/1994 the number of claims by abattoir workers for Q fever (it is a compensable illness in Australia) declined from 139 per year to 2 in 2003/2004.[41]

Another aspect of Q fever that was first recognized and defined in Australia is that of post Q fever fatigue syndrome.[42] It was also reported about the same time from the United Kingdom.[43] The designation, Q fever fatigue syndrome (QFFS), is now used to describe the protracted state of fatigue that can develop in up to 20% of patients who develop acute infection with *C. burnetii*.[42,44] Q fever fatigue syndrome consists of a constellation of symptoms including fatigue, headaches, sweats, arthralgia, blurred vision, muscle fasciculations and enlarged and painful lymph nodes.[42] In a case–control study 5 years after a large outbreak of Q fever in individuals in a community in the West Midlands, United Kingdom, Ayres et al.[45] found that participants who were diagnosed with acute Q fever during the initial outbreak had more complaints of fatigue, sweats, blurring of vision and dyspnea than their age, sex and geographically matched controls and that 42.3% of the infected individuals fulfilled the CDC criteria for chronic fatigue state. Although not conclusive, there is evidence to suggest that "cytokine dysregulation and immunomodulation from persistence of *C. burnetii*" in the host may be responsible for QFFS.[44,46]

Hatchette et al.[47] prospectively followed 49 patients with goat-related Q fever in Newfoundland. The Short Form 36 Health Survey was used to assess the quality of life. Thirty-eight percent (19/49) who had acute Q fever during the outbreak had persistent symptoms 3 months later and had significantly lower scores on all components of the SF-36 than those who did not have persistent symptoms. Two years after the initial outbreak 30% (10/33) of the participants who had serologic evidence of *C. burnetii* infection continued to report persistent symptoms compared with 4% (1/24) of those who did not have Q fever.[47] Helbig et al.[48] compared variability in phenotype distribution among a range of cytokine and accessory immune response genes in 23 patients with post Q fever fatigue syndrome and in 42 Red Cross blood donors from Adelaide, Australia. They found that there were significantly more variants in the natural resistance-associated macrophage protein gene among the patients compared with the controls. In addition there were significant differences in the IL-10 promoter and in intron 1 of the interferon γ gene. HLA DR-11 was present in 19.6% of the cases and 4.3% of the controls ($p = 0.0014$). All of this indicates that there may be a genetic basis for the post Q fever fatigue syndrome.

Hickie and colleagues[49] enrolled 253 patients with Epstein–Barr virus infection ($n = 68$), Q fever ($n = 43$), Ross River virus infection ($n = 60$) and an unconfirmed group ($n = 82$) in a prospective longitudinal study to determine the frequency of chronic fatigue following each of these acute infections and the factors that predict the fatigue state. The case rates for post-fatigue syndrome at 6 weeks, 3, 6 and 12 months were 35, 27, 12 and 9%, respectively, with no difference in case rates between the initial infective agents. Overall there were 29 cases with post-infective fatigue, one was excluded. The initial infection was EBV 5 (7.3%), Q fever 3 (6.9%), RRV 13 (21.6%) and unconfirmed infection 8 (9.7%). These investigators concluded that aspects of the host response rather than the infecting agent is the likely determinant of the post-infective fatigue syndrome.

It is noteworthy, however, that the author of this chapter has treated approximately 300 patients with Q fever pneumonia in Nova Scotia secondary to exposure to infected parturient cats. None of these persons developed QFFS. In the same province one person, following exposure to soil contaminated by goat manure, developed severe QFFS. Thus it is likely that there may be organism, vector and human host factors involved in whether or not QFFS is a sequela of acute Q fever.

The cost of Q fever to the Australian economy has been estimated at $1 million annually and there is a loss of more than 1,700 weeks from work.[39]

5.1.4. France – Including Age and Sex Distribution. The WHO Rickettsial Laboratory under the direction of Didier Raoult in Marseille has been a source that has added greatly to our understanding of not only the epidemiology of Q fever but also the basic science of this infectious disease.

Countrywide studies of the epidemiology of Q fever in France have not been preformed. Nevertheless it is apparent that France (especially the South of France) is one of the countries with the highest incidence of Q fever in the world. In some areas of this country the incidence is 500 per million persons per year.[50] Raoult and coworkers[51] reported their experience with 1,383 cases of

Q fever from 1985 to 1998. They noted that 1,070 (77%) of the cases were acute Q fever, but a remarkable 23% or 313 people had chronic Q fever. Among the acute cases, hepatitis dominated accounting for 40% of the cases; pneumonia and hepatitis 20%; pneumonia 17%; isolated fever 17%; meningoencephalitis 1%; myocarditis 1%; pericarditis 1%; meningitis 0.7%. Most of the patients with chronic Q fever had infective endocarditis 259/313 (83%); 25 had infection of a vascular aneurysm or prosthesis, 15 had Q fever during pregnancy and 7 had osteoarticular infection. They noted that hepatitis occurred in younger patients and pneumonia in older and more immunocompromised patients and that isolated fever was more common in female patients. It should be noted that they accumulated their cases from their role as a reference laboratory wherein they tested 74,202 serum samples for Q fever over this time period. It is thus difficult to know if some of their observations such as hepatitis occurs in younger patients and pneumonia in older patients are correct and not a result of testing bias. There is emerging evidence that the dominant manifestation of acute Q fever has at least a geographic basis. In Nova Scotia, Canada, most cases of acute Q fever are pneumonia.[52] Nearly all of these were due to exposure to infected cats. In the Basque region of Spain, the manifestations of Q fever were almost equally hepatitis and pneumonia.[53] In the south of Spain in a study of 231 cases between 1985 and 1999, 231 (90%) presented with fever and 148 (64%) had hepatitis.[54]

There are two potential explanations for the different manifestations of the disease according to geographical location. One is that different strains of *C. burnetii* result in different disease manifestations. The French group has taken epidemiology to the molecular level by typing 173 isolates of *C. burnetii* collected from around the world. They used multi-spacer sequencing of the entire genome to type the organisms.[55] They were able to resolve all of the isolates into three monophyletic types. Group 1 consisted of 13 sequence types with isolates from France, Russia, Spain, Kyrgystan, Nambia, Kazakhstan, Ukraine, Uzbekistan and United States. There were two subgroups in monophyletic type 1 with 36 isolates from eight sequence types in the first and 39 isolates from five sequence types in the second. Group 2 isolates were from France, Germany, Switzerland, Romania, Italy, Greece, Austria, Slovakia, United States, Russia, Africa, Kazakhstan, Uzbekistan, Mongolia and Japan. It was divided into four subgroups. Monophyletic group 3 consisted of only one sequence type with 10 isolates. Seven of these were from Nova Scotia patients, two from France and one from United States.

The other potential explanation for the differing manifestations of acute Q fever in different geographic regions is that the route of infection might have a role to play. Thus ingestion of contaminated milk might result in hepatitis and inhalation of contaminated aerosols could result in pneumonia. There is some experimental evidence that supports this.[56]

The French group made two other major contributions to the epidemiology of Q fever. The predominance of Q fever among males has long been accepted as due to the fact that predominately male occupations (animal herders, abattoir workers, animal shearers, farmers, etc.) were associated with the traditional risk factors for Q fever. It is noteworthy that this gender bias is not evident among Q fever cases in children.[57] When C57/BL6 mice were injected with *C. burnetii,* bacterial load and granuloma numbers were lower in females than in males.[58] However, oophorectomized mice had the same bacterial load as males. Treatment of oophorectomized mice with 17 beta-estradiol reduced the bacterial load and number of granulomas in these mice. These findings led the authors to conclude that female sex steroids are protective against Q fever.

The French group was able to demonstrate that *C. burnetii* could be spread at least 11 km downwind from a contaminated source.[59,60] This finding has been confirmed by a group from the United Kingdom.[61]

Two other major contributions of the WHO Rickettsial Laboratory in Marseille to the study of the epidemiology of Q fever are the development of the shell vial technique for the isolation of *C. burnetii* from a variety of biological samples[62] and development of a polymerase chain reaction for the application of *C. burnetii* DNA thereby allowing for molecular diagnosis of this infection.[63]

5.1.5. United Kingdom. In 1958 Marmion and Stoker[64] noted that there had been 104 cases of Q fever in humans in Great Britain and that the peak months for infection were April, May, June, July and October. This group also noted that 6.9% of herds of cattle tested in England, 2% in Wales and 0.8% in Scotland were infected with *C. burnetii* as judged by isolation of the organism. In 1956 Marmion and Stoker[65] described the role of contaminated fomites in the spread of Q fever when they investigated an outbreak of Q fever among 10 amateur actors who had performed a play at a village church at Easter 1949. A shepherd who had a role in the play came to rehearsals with his dog and he was still dressed in his working clothes. They were able to isolate *C. burnetii* from one specimen of dust collected from the clothing of the shepherd.

Palmer and Young[66] reported on all cases of Q fever endocarditis in England and Scotland between 1975 and 1981. They noted that Q fever endocarditis accounted for 11% (92/839) of the cases of Q fever and for 3% of all cases of endocarditis during this period.

Early on in the study of Q fever in Great Britain, Stoker and Marmion[67] noted that man was the only animal species

to regularly develop illness when infected with *C. burnetii*. They also noted that while *C. burnetii* has been isolated from 22 species of ticks, transovarial passage was achieved in only 4 species suggesting that *C. burnetii* cannot be maintained indefinitely in successive generations of its arthropod host without re-infection from another host.

From 1984 to 1994, 1,117 cases of Q fever were reported from England and Wales.[68] The mean age was 45 years and 75% were men. Contact with animals, mainly cattle and sheep, was reported in 60% of cases. Occupationally acquired infection was reported for 24 cases and included abattoir workers, farmers, veterinary surgeons, hide handlers and butchers. Forty-seven percent presented with respiratory symptoms, 7% with heart disease and 5% with hepatitis. Seven percent reported traveling abroad before becoming ill.

Recent events in the epidemiology of Q fever in Great Britain include a July 2002 outbreak at a packing plant in Newport Dock in South Wales.[69] In this outbreak 59/214 (27.5%) of the employees were infected. The plant manufactured corrugated cardboard products and no source for the Q fever was found. From July 9 to July 24, 2006, 24 persons who worked at a meat processing company in Bridge of Allan, Stirlingshire, Scotland, developed Q fever.[70]

5.1.6. Q Fever in Other Countries. *Coxiella burnetii* has been an extraordinarily successful pathogen. By 1955 it was found in 51 countries on five continents.[71] Indeed by the 1990s New Zealand was one of the few countries that were free from *C. burnetii* infection.[72] Arricau-Bouvery and Rodolakis[72] reviewed 18 major outbreaks of Q fever from 11 countries that had been reported from 1999 to 2004. The countries involved were France, five outbreaks; Australia, two outbreaks; Italy, two outbreaks; Japan, two outbreaks; Bosnia, Israel, French Guiana, Canada (province of Newfoundland and Labrador), The Netherlands, Germany and Kenya, one each. Goats were the implicated source in nine, goat manure three, travel associated two, dogs and cats one, wild reservoir one and unknown one.

5.2. Q Fever, the Military and Bioterrorism – Including Contagiousness

Christopher et al.[73] noted that Q fever may have been a significant factor during the American Civil war. During World War II outbreaks of Q fever occurred among American and British soldiers in Greece and Italy. American soldiers in Panama also developed Q fever. Some members of the Axis troops serving in Bulgaria, Greece, Crimea, Bulgaria and the Ukraine developed Q fever. Seven outbreaks of Q fever occurred among US troops in the Mediterranean theater resulting in more than 1,000 serologically confirmed cases. Cases were epidemiologically linked to occupancy of barns and two story dwellings where the bottom story served as a barn. After World War II an explosive outbreak occurred among troops in Libya and most recently cases were acquired during operation Desert Storm. In 2003, 3 of 19 cases of severe pneumonia among American Soldiers serving in Iraq were due to *C. burnetii* and later 5 more cases of Q fever infection were documented.[74]

Q fever was diagnosed at four UN stabilization bases in Bosnia and Herzegovina in 1997.[75] There were 26 cases with an overall attack rate of 4.6%. Five soldiers had pneumonia. A sheep farm was located 100 m from the base. Helicopters landing nearby may have generated aerosols and may have been the source of the outbreak.

Coxiella burnetii is a CDC category B bioterrorism agent.[76] Category B agents have the potential for large-scale dissemination but generally cause less illness and death than category A agents.[77] As a biological warfare agent, *C. burnetii* can be easily dispersed as an aerosol with a high infectivity rate and pneumonia as the major manifestation. The possibility that *C. burnetii* could be used as a bioterrorism agent has resulted in renewed interest in the dynamics of aerosol transmission of this microorganism. It has been calculated that a concentration of 100 cells per m^3 and an exposure time of 30–60 min can deposit more than one cell in the lung and hence result in infection.[78]

5.3. Epidemiology of Q Fever at the Community Level

The study of outbreaks using "shoe leather" epidemiology at the community level has given us much of our information about Q fever. The story of Q fever in Nova Scotia, Canada, illustrates this very well. Q fever was first recognized in Nova Scotia in 1979 during a study of atypical pneumonia.[79] Before too long it was evident that Q fever was occurring in small outbreaks involving family units. Empiric observations and a case–control study as well as isolation of *C. burnetii* from parturient cats associated with these outbreaks confirmed the hypothesis that Q fever was associated with exposure to parturient cats and stillborn kittens in this province.[80–83] Surprisingly in 1990 outbreaks of Q fever in Nova Scotia seemed to cease. Sporadic cases continue to occur but it is now rare to see outbreaks associated with infected parturient cats. Outbreaks of Q fever associated with exposure to infected parturient cats also occurred in the neighboring provinces of Prince Edward Island and New Brunswick. There was also such an outbreak in Maine.[84] There is a suggestion that cats may be associated with Q fever in Japan.[85] Many of those who became ill in Nova Scotia following exposure to infected parturient cats had pneumonia. Radiographically this manifested as single- or multiple-rounded opacities. Most of the patients were

moderately to severely ill and required hospitalization. Improvement occurred rapidly following the administration of appropriate antibiotic therapy. Reactive thrombocytosis occurred in about half the patients with platelet counts reaching 1 million per mm^3. There was only one death among about 300 patients with Q fever pneumonia and that patient had concomitant aspiration pneumonia and probably died from gram-negative sepsis. During the time when cat-related outbreaks of Q fever were occurring the incidence of Q fever in NS was very high at 50 cases per million persons per year.

Cases of Q fever in NS were also associated with exposure to rabbits, deer and cattle.[86–91]

In 1995 we noted our first outbreak of Q fever due to exposure to an infected parturient dog; however, dog-associated Q fever seems to be exceedingly rare.[92] In 2006, a case of Q fever pneumonia as a result of contact with infected parturient sheep occurred in Nova Scotia. This person has experienced considerable fatigue following recovery from the pneumonia. In a survey carried out in 1982 only 6.7% of 329 sheep tested had low levels of antibodies to *C. burnetii*.[93] As part of the investigation of the sheep-associated case of Q fever in NS in 2006 blood from 30 ewes was tested and over 50% had antibodies to Q fever. In a study carried out in 1984, 49% of 65 veterinarians and 35% of 96 slaughterhouse workers tested had antibodies to phase II *C. burnetii* using the microimmunofluorescence test.[81] Contrast this with the seroprevalence of 11.8% among 997 blood donors in NS in 1982.[94]

No cases of Q fever had ever been diagnosed in Newfoundland until 1999. At that time an investigation of an outbreak of abortions among goats revealed that 66/179 goat farmers, their family members and farm workers had acute Q fever.[95] About 1 year previously the community of Bonavista imported goats from Ontario, Prince Edward Island and Maine to start a goat-farming co-operative. At the time of the investigation most of the goats were infected. The clinical manifestations were mainly those of a self-limited febrile illness.[95] However, there was a secondary case that was most unusual.

One of the workers had her clothes washed at home; her mother, a 53-year-old lady, underwent coronary artery angioplasty 6 days before the onset of the symptoms of acute Q fever. Within 4 months she demonstrated the serological profile of chronic Q fever.[96]

Q fever is relatively uncommon in Alberta, Canada, but in recent years there have been 3–6 cases per year. The epidemiological associations are with exposure to goats and sheep. Interestingly, urticaria that persists for 6 or so weeks has been a prominent part of the Q fever illness in three patients (Marrie TJ – unpublished observations).

There have been many outbreaks, over the years, which provide additional information about the epidemiology of Q fever. British residents who lived along a road over which farm vehicles traveled developed Q fever as a result of exposure to contaminated straw, manure or dust from farm vehicles.[97] Four hundred and fifteen residents of a Swiss Valley who lived along a road over which sheep traveled to and from mountain pastures developed Q fever.[98] Those who lived in six villages close to the road had high rates of infection, ranging from 11.8 to 35.8% (mean 21.1%), while those who lived in villages off the road had significantly lower rates of infection, range 2.1–6.8% (mean 2.9%). A recent paper by Senn[99] reviews the above outbreak and concludes that techniques of statistical analysis developed for analysis of experiments, for which the usual precautions of randomization ensure independence, are not necessarily appropriate to the analysis of epidemics. An outbreak of Q fever involving 58 persons in Northern Italy was associated with three flocks of sheep that passed through the area between late May and early June.[100] The prevalence of *C. burnetii* antibodies in these flocks ranged from 45 to 53%. A very similar event was attributed as the cause of an outbreak of Q fever in a prison in Italy wherein 65/600 inmates were infected.[101] Yet another outbreak occurred in Northern Italy at a private residential community for the rehabilitation of drug users.[102] Two hundred and thirty-five of the residents developed Q fever in two consecutive outbreaks. Both outbreaks occurred just after lambing. Forty percent of the 828 or so residents were HIV positive. They were able to show that there was no difference in the manifestations of Q fever according to HIV status and there were no relapses or chronic infection.[102]

Increasingly urban residents visit farms for a variety of reasons. Such visits can result in Q fever as described in Southern France.[103]

On May 3 and 4, 2003, people visited a farmers' market in a spa town close to Soest, Germany, where a sheep had lambs.[104] Subsequently 299 cases of Q fever were linked to this event. The mean incubation period was 21 days with an interquartile range of 14–24 days. About 25% of the adult population was infected compared with 5% of the children and 25% required hospitalization.[104] The implicated ewe was seropositive for *C. burnetii.*

As our use of animal products changes so too does the epidemiology of Q fever. A small factory, employing eight persons, in Victoria, Australia, manufactured powdered sheep placenta and fetal tissue for the cosmetics industry. In February 2005 as a result of a request for amniotic fluid the manufacturing process was changed and four employees developed Q fever.[105]

In a town in France, 29 cases of Q fever occurred due to aerosols created by helicopters landing close to a slaughterhouse with uncovered sheep waste.[106] In 1951 Harvey and colleagues[107,108] reported a unique outbreak of Q fever at a

College in Cambridge, England. They attributed the outbreak to straw in a packing case.

Even an activity such as playing poker can result in Q fever if your infected cat gives birth to kittens in the immediate vicinity of the poker game.[109]

Reilley and co-workers[110] reviewed all cases of Q fever that had occurred over 16 years in their hospital catchment area. Their investigations uncovered some old and some new sources for Q fever. Thus eight persons developed Q fever following renovations on former farm buildings. They felt the source was disturbance of contaminated dust during renovation work. Two members of a film crew developed Q fever following exposure to windborne straw and peat.[110] This report is remarkable because of the high rate of neurological complications that ensued in the patients with Q fever.

In the summer of 1981, 29 patients living in Gwent, South Wales, had Q fever.[111] Twenty were diagnosed by routine clinical and laboratory services and nine were discovered by active case finding. The date of onset of symptoms spanned a 1–2-month period. The peak incidence was at the end of June. A case–control study showed an association with one area on the outskirts of Newport. Most patients had no direct contact with farms or farm animals and a common source of infection could not be identified. The most likely explanation of the outbreak was that farm vehicles had disseminated contaminated straw, manure or dust in the area of Newport adjacent to farmland. The last straw episode is one from an outbreak of Q fever in South Wales, United Kingdom, from July 15 through September 30, 2002.[112] Ninety-five of 282 (33.6%) employees of a cardboard manufacturing plant developed Q fever. The offices were undergoing renovation and drilling into contaminated straw board was felt to be the likely source of the outbreak.

One of the largest case series of Q fever was from Bulgaria.[113] Until 1990 there were more than 20 outbreaks per year, some with hundreds of patients. Q fever has been known in Slovakia since 1954 when outbreaks occurred among agricultural workers who contracted infection from sheep imported from Romania.[113] From 1954 to 1980 waves of epizootics and small epidemics appeared in factories processing cotton, wool and hides from Mongolia and China. Since the 1980s only sporadic cases have occurred. Mass vaccination of cattle was carried out in Slovakia in the 1970s.

There have also been outbreaks of Q fever where unusual sources have been postulated with less than clear evidence of a cause-and-effect relationship.[114] One such outbreak involved 16 cases among family members or visitors to a farm in South Kent. A piglet bitten by a rat was nursed in the farmhouse and was handled by a man who was one of those who were infected. However, a sow also aborted within the time frame for the incubation period for Q fever. Also of interest was that the patients were treated with chloramphenicol with a good response. Another unusual outbreak was one that occurred in a hospital kitchen in Israel.[115] Sixteen cases occurred over 42 days among the 41 staff members. No clear source for the infection was found although it was postulated that a contaminated ventilation shaft or contaminated clothing was the source.

The first case of Q fever in Uruguay was described in 1956 in a slaughterhouse worker. Fourteen outbreaks, involving 1,358 suspect clinical cases, were studied between 1975 and 1985. All occurred among workers at meat-processing plants. The incubation period ranged between 13 and 21 days.[116]

A prospective study was designed to determine the occupational risk of Q fever in five English local authority districts.[117] The seroprevalence of Q fever was measured and the cohort followed for 2 years. There were no seroconversions during the first year but two occurred during the second year for an incidence of 813/100,000 per year (95% confidence intervals 98–2,937/100,000 per year). Seroprevalence was higher among the study cohort 105 of 385 versus 43 of 395 (27.2%) compared to 43 of 395 (10.8%) among other UK farm workers ($P < 0.01$). The authors concluded that the risk of Q fever on livestock farms is related to contact with the farm environment rather than any specific animal exposure. They also indicated that the absence of an increasing prevalence with age suggests that exposure may occur as clusters in space and time, i.e., outbreaks.[117]

A prospective surveillance study in Cyprus also adds to our knowledge of the epidemiology of Q fever.[118] Before considering the current study it is worthwhile knowing something about the background of Q fever in Cyprus. It was first identified in this country in 1951[71] and serosurveys in 1968 and 1969 demonstrated that 5% of 547 patients at Nicosia General Hospital had antibodies to *C. burnetii*.[118] From December 1974 to June 1975, 78 British soldiers in Cyprus developed Q fever as a result of exposure to contaminated dust from an abortion epidemic among sheep and goats due to *C. burnetii*.[119] At that time no cases were reported from the local population. In the current study[118] seropositive humans and animals in two villages were identified and then all seronegative individuals were followed for 1 year on a monthly basis. Eighty-one humans and 239 animals from both villages participated in the first phase. Two humans and one goat were identified as having clinical Q fever; however, 44.4% of the humans and 13.8% of the animals were seropositive at the end of 1 year. During the second phase of surveillance, nine human, eight goat and four sheep cases

were serologically confirmed and *C. burnetii* was isolated from three human and two animal samples for an incidence rate among humans of 1.2/100,000 per year.[119] In another study of Q fever in Cyprus, Psaroulaki et al.[120] obtained serum samples from 583 humans, 974 ruminants and collected 141 ticks from animals. They used PCR to detect *C. burnetii* DNA in the ticks, and a geographical information system was used to identify high-risk regions. The seroprevalence for Q fever was 52.7% for humans, 48.2% for goats, 18.9% for sheep and 24% for bovines. Just over 11% of the ticks had *C. burnetii* DNA. Using the geographic information system they identified two high-risk villages. The risk factors for *C. burnetii* infection among humans were age, residence, occupation, use of manure in garden, ownership of animals (especially goats) and the presence of tick infested or aborting animals.

5.4. Q Fever in Animals

As is evident by now Q fever is a zoonosis and direct or indirect contact with infected cattle, sheep, goats, cats and dog or the products of conception of these animals are the primary source of Q fever for humans. Contamination of the environment by fluids from these animals is also an important source of Q fever for man. A full understanding of the epidemiology of Q fever in humans requires knowledge about coxiellosis in animals. *C. burnetii* localizes to the uterus and mammary glands of infected animals[121] Infected cows can shed *C. burnetii* in milk for up to 32 months.[122] Large concentrations of *C. burnetii* are present in the infected placenta, and aerosols are created during parturition.[123] Inhalation of these contaminated aerosols by a susceptible human, results in Q fever.

Coxiella burnetii infection has caused outbreaks of abortion in goats[121,122] and sheep.[123,124,125] Sanford et al.[123] described abortions that occurred in five goat herds that were exposed to three goats from another herd that kidded prematurely during a fair. All of the goats were housed in the same barn. Abortions began in the exposed herds 21 days after the exposure and affected 20–46% of the pregnant animals in each herd. Immunohistochemistry methods have shown that organisms are present on both surfaces of the chorioallantoic membrane of the affected placenta.[126] The placentas of infected sheep can contain 10^9 guinea pig infective doses of *C. burnetii* per gram of tissue.[127,128]

The stillbirth rate among infected cats is about 70% compared with the usual rate of 10% for uninfected cats.[129]

Dairy cows are important in the spread of Q fever, while beef cows are rarely infected.[130] Once *C. burnetii* is introduced into a herd rapid spread occurs; so that 80% of the cows are positive within a few months.[131] Infected wildlife may be important in infecting cattle since in a large portion of newly infected herds a source of infection is not found.[131,132]

Hares and rabbits in many areas have the highest rate of infection among wild animals.[132] In a study in Oxfordshire, Webster et al.[133] found that 7–53% of wild brown rats (*Rattus)* were seropositive for *C. burnetii.* These workers postulated that since cats are frequent predators of rats this explains why cats become infected.

Infected ticks are probably most important in keeping the whole cycle of *C. burnetii* infection going.[67,118] Infected ticks have been found on rabbits, goats, cattle, sheep and many other animals.[67,118] It is likely that birds are also important in the spread of *C. burnetii* by transporting infected ticks from one area to another. Birds may also be involved directly in the spread of Q fever to man as evidenced by a recent outbreak of Q fever among family members in Southern France due to aerosols from *C. burnetii* infected pigeon feces.[134]

In some countries infection among domestic or wild animals results in considerable infection among humans in contact with these animals, whereas in other areas little if any transmission to man occurs.[64]

Ewes shed *C. burnetii* in vaginal mucus and feces more often and for a longer time than cows however cows and goats shed the organism for a longer time in milk.[135] Berri et al.[136] noted two abortions associated with *C. burnetii* infection among a group of 34 pregnant ewes managed by the experimental Infectious Pathology and Immunology unit of the institute in Tours-Nouzilly, France. They treated the ewes with oxytetracycline to prevent spread of the infection and further abortions. However 5 abortions occurred in January and March 1999 in three groups of ewes and 24 of the ewes shed *C. burnetii* in vaginal secretions. Twelve percent of 113 lambs born in 1999 were seropositive for *C. burnetii* and half of the seropositive lambs were born to either seropositive ewes or dams that excreted the pathogen in their vaginal tracts. However in 2000 all 150 lambs were seronegative.[136]

In goats active *C. burnetii* infection seemed to be limited to two pregnancy cycles.[137] Berri et al.[136] found that following a first kidding season when only 57% of 56 pregnant goats had a normal delivery in the second season 87% had a normal delivery. They noted that goats shed *C. burnetii* in milk for 3 months.[136,138] The Berri group[139] also noted that goat manure used as garden fertilizer can be a source for Q fever in humans.

In cattle metritis is a unique manifestation of this infection.[140] We were able to associate an outbreak of Q fever in a town with metritis due to this organism in a cat.

6. Routes of Transmission

6.1. Inhalation of Contaminated Aerosols

Experimental and epidemiological evidence lead to the conclusion that this is the major mechanism whereby Q fever is transmitted to man.[59–61,141–145] Volunteers who inhaled one infectious dose had an incubation period of 16 days, whereas those who were exposed to 1,500 infectious doses had an incubation period of 10 days.[141] Indirect exposure to contaminated material may also lead to Q fever such as when contaminated clothing from the Rocky Mountain laboratory in Montana led to cases of Q fever among laundry workers.[142] Another unusual outbreak of Q fever occurred among factor workers who were handling contaminated imported cotton.[143] There have been several outbreaks of Q fever in research institutions when infected pregnant animals, especially sheep, were transported through the building to the laboratory.[144–147] Carefully conducted studies have documented that high winds can result in infection with *C. burnetii* up to 11 miles (18.3 km) distant from the point source.[59–61] A petting zoo in two shopping malls in Quebec, Canada [13 goats and 5 sheep on exhibit between March 25 and April 3, 1999] was the source of 95 cases of Q fever.[148]

6.2. Oral Route

There is a suggestion from epidemiological studies that ingestion of contaminated milk is a risk factor for Q fever infection.[149–153] However, evidence from experiments where contaminated milk was fed to volunteers is contradictory.[151–153] In a case–control study Hatchette and co-workers[154] found that ingestion of pasteurized cheese and tobacco smoking were both risk factors for acquisition of Q fever during an outbreak of Q fever on caprine cooperative farms in Newfoundland.

We feel that the route of infection may explain the difference in the manifestations of Q fever in some countries, e.g., pneumonia in Nova Scotia, Canada versus hepatitis in Marseille, France.[155] We used five different strains of *C. burnetii* to infect mice via the intraperitoneal or intranasal route. Those infected intranasally developed pneumonia only, while those infected intraperitoneally developed hepatitis, splenomegaly and pneumonia. Bronchiolar changes were seen only in mice inoculated intranasally.[155] These data have been reproduced in a guinea pig model of Q fever.[156]

6.3. Percutaneous Route

Crushing an infected tick between the fingers has resulted in Q fever[157] and blood transfusion.[158]

6.4. Vertical Transmission

This occurs rarely but increased surveillance may reveal additional cases of vertical transmission.[159–161] In the town of Martigues in Southern France Q fever complicated at least 1 in 540 pregnancies.[161]

6.5. Person-to-Person Transmission

Despite the fact that pneumonia (and hence the potential for spread via aerosols) is a common manifestation of Q fever in man there have been only a few cases of person-to-person transmission.[162–164] The intracellular location of the organism is likely the explanation for this. There are two reports of transmission of Q fever to attendants during autopsies,[162,163] and one report of transmission of infection from a patient to hospital staff.[164] Since infected parturient cats, sheep and cattle readily spread infection to man – one wonders why more cases of Q fever do not develop in obstetrical staff who assist at the delivery of infected pregnant women. We have observed two pregnant women with large numbers of *C. burnetii* in the placenta yet Q fever did not develop in any of the obstetrical attendants, however Stein and Raoult[160] did document Q fever in an obstetrician who attended the delivery of a woman with Q fever during pregnancy. Nevertheless person-to-person transmission is so infrequent that patients with Q fever are not isolated when they require admission to hospital for treatment.

6.6. Sexual Transmission

Sexual transmission of *C. burnetii* has been demonstrated in mice[165] and viable *C. burnetii* cells have been demonstrated in bull semen.[166] There has been speculation that Q fever can be sexually transmitted among humans.[167] Milazzo et al.[168] reported the case of a 53-year-old man who developed orchitis as a complication of Q fever. The orchitis had its onset 3 days after he had intercourse with his spouse (29 days after onset of his illness). Fifteen days later his spouse developed Q fever. *C. burnetii* DNA was identified by PCR in the semen of the index case 4 and 15 months after onset of the acute illness. These data indicate that *C. burnetii* can be transmitted sexually in humans.

7. Biological Characteristics of the Organism: Pathogenesis and Immunity

The interaction of *C. burnetii* with the human host is a fascinating story in bacterial pathogenesis that is still incompletely understood.[15,169–178] The T-cell-dependent immune control of *C. burnetii* does not lead to its eradication and thus immunosuppression can induce relapse of infection in apparently cured patients or laboratory animals.[46,48] Recently, Harris et al.[46] showed that *C. burnetii* DNA could be demonstrated by PCR in circulating monocytes and bone marrow months or years after acute Q fever. These findings in conjunction with a certain host response could explain why chronic Q fever and persistent fatigue syndrome occur.[42–43] Another key observation which relates to the immune response to *C. burnetii* is that very few organisms and a strong cellular response are seen in patients with acute Q fever, while many organisms and a moderate cellular response are seen in patients with chronic Q fever.[177]

8. Patterns of Host Response

Q fever can be broadly divided into two major categories, acute and chronic. Acute Q fever is easily managed and most cases are self-limited and indeed are not recognized either by the patient or by the physician. Chronic Q fever is a serious condition with considerable morbidity and mortality. Most cases of chronic Q fever are endocarditis. The clinical manifestations of Q fever are summarized briefly here but are referenced so that interested readers can read more.

8.1. Acute Q Fever

There are several manifestations of acute Q fever:

8.1.1. A Self-Limited Febrile Illness. This is the most common manifestation of acute Q fever. Most individuals who fall into this category do not know that they have had Q fever. The illness is considered to be one of the many non-specific illnesses that one suffers from during life. Occasionally fever is prolonged and necessitates hospitalization and a fever of unknown origin workup.[181,182]

8.1.2. Pneumonia. This manifestation of acute Q fever differs according to geographic site. The manifestations of pneumonia are the same as for any other pathogen – fever, cough (usually non-productive) and in severe cases shortness of breath. The radiographic manifestations are often distinctive and show single- or multiple-rounded opacities.[183–189]

8.1.3. Hepatitis. In most instances the hepatitis is manifested as elevated liver enzymes. Occasionally jaundice is the presenting manifestation of Q fever. Prolonged fever is not unusual in patients with Q fever and hepatitis. This fever frequently does not respond to antibiotic therapy and a short course of corticosteroid therapy is necessary.[190–199]

8.1.4. Miscellaneous Manifestations. At times manifestations other than the three mentioned above dominate the clinical picture. Thus the presentation could be that of central nervous system infection; peri or myocarditis; lymphadenopathy, splenic rupture or orchitis.[199–209]

8.1.5. Q Fever in Immunocompromised Host. Q fever can occur in the immunocompromised host. Most clearly documented to date is infection in patients with human immunodeficiency virus infection. Recently there has been a case report of Q fever pneumonia in a patient with a renal transplant.[210–215]

8.2. Chronic Q Fever

There are six main presentations of chronic Q fever

1. Endocarditis – about 90% of the cases of chronic Q fever are endocarditis. The diagnosis and management of this condition are difficult. The current therapeutic regimen of choice is doxycyline plus hydroxychloroquine.[216–240]
2. Endovascular infection.[241]
3. Osteomyelitis.[242]
4. Q fever in pregnancy.[243–246]
5. Hepatitis – most of the cases of hepatitis due to *C. burnetii* are manifestations of acute Q fever. On occasion, however, hepatitis can be chronic.[51]
6. Miscellaneous manifestations – these include livedo reticularis, chronic thrombocytopenia and mixed cryoglobulinemia.[51]

9. Control and Prevention

9.1. General Concepts

Good animal husbandry practices are the primary methods in preventing widespread contamination of the environment by *C. burnetii*. Prevention of zoonotic spread is best accomplished by isolating aborting animals for up to 14 days, raising feed bunks to prevent contamination of feed by excreta, destroying aborted materials by burning and burying fetal membranes and stillborn animals and by wearing masks and gloves when handling aborted materials.[247,248] Treatment of infected animals with tetracycline compounds may also have a role in limiting the spread of *C. burnetii* infection. There are insufficient data on vaccination of animals to know whether or not this strategy has a role in limiting spread of Q fever.

Only seronegative pregnant animals should be brought into the facilities where research will be done. In addition only seronegative animals should be used in petting zoos.

9.2. Chemotherapy and Prophylaxis

The major role for prophylaxis is in the event of widespread contamination such as from a bioterrorism event. The European guidelines recommend prophylaxis within 1 week of exposure with doxycycline 100 mg bid po.[247] Other choices are erythromycin, clarithromycin or roxithromycin. The treatment of acute and chronic Q fever is outlined in Section 8.

9.3. Immunization

Coxiella burnetii vaccines are not generally available. However, Q vax (heat-inactivated phase 1 cells) has been used very successfully in Australia. Potential vaccines should be antibody and skin test negative for *C. burnetii* to avoid adverse reactions. Sterile abscess at the site of injection is the most common and most severe adverse reaction. High-risk groups (in endemic areas) such as abattoir workers, veterinarians, laboratory workers who isolate *C. burnetii* should be immunized.[248,249] While a Q fever vaccine is not available commercially in the United States, such a vaccine is available from the Centers for Disease Control.[248] Marmion has recently reviewed the history of Q fever vaccine in Australia and briefly discussed chemovaccine (used in Eastern Europe) and the search for newer vaccines.[250]

10. Unresolved Issues

There are many unresolved issues regarding Q fever. Why does the epidemiology vary from country to country and even within a country? Why does the rate of Q fever post-fatigue syndrome vary from country to country? Other unresolved issues include policies on surveillance of animals and regulation of sale of seropostitive animals.

CHAPTER 31

Rocky Mountain Spotted Fever

Aaron Milstone and J. Stephen Dumler

1. Introduction

Rocky Mountain spotted fever is an acute febrile illness transmitted to man by ticks infected with *Rickettsia rickettsii*. Usually sudden in onset, it is characterized by chills, headache, and fever lasting 2 or more weeks. A characteristic rash appears on the extremities on about the 4th febrile day and spreads to the trunk. The exanthem and other anatomical manifestations result from focal areas of vasculitis and perivascular inflammation scattered throughout the body. Central nervous system (CNS) manifestations of delirium and coma as well as shock and renal failure occur in the severely ill. Serum antibodies to specific rickettsial antigens appear during the 2nd and 3rd weeks of illness. The tetracyclines are highly effective therapeutically.

2. Historical Background

Idaho physicians described a form of "black measles" in the Snake River Valley as early as 1873. In 1899, Maxcy described a febrile illness with delirium and a blotchy-skin, red–purple–black rash that appeared first on the ankles, wrists, and forehead, with rapid general body spread. This was the "spotted fever of Idaho." It was noted to be sporadic and more common in the spring, and local opinion attributed it to the drinking of water from melted snow or inhalation of sawdust.[1] Dr. Earl Strain, a practicing physician in Great Falls, Montana, first suspected the role of ticks, having noted a relationship between a death and a history of a tick bite. Wilson and Chowning[2] concurred with this relationship and concluded that the disease was transmitted by a local wood tick and the ground squirrel (gopher) as a possible reservoir.

In concert with the prevailing opinions of the times regarding tick-transmitted infections, they proposed *Piroplasma hominis*, an erythrocyte parasite, as the causative agent. In a series of brilliant studies carried out from 1906 to 1909, usually during the spring and summer months, Howard Taylor Ricketts successfully transmitted the disease to guinea pigs and monkeys by inoculation of blood from patients with spotted fever, incriminated the wood tick, *Dermacentor andersoni*, as vector by feeding experiments on animals and demonstrated the occurrence of naturally infected ticks.[3] He observed bacteria-like bodies in smears prepared from tick tissues and showed the transovarial transmission of infection to offspring of infected female ticks. Ticks were shown to be infected throughout their life span. Studies of immunity showed that blood from animals that survived the infection protected other animals if blood was administered several days before infection.[4,5] Wilder and Ricketts showed through cross-immunity studies that spotted fever and typhus were distinct entities. Ironically, the Montana legislature in 1909 allocated the sum of $6,000 for Rickett's research studies, which the board of examiners failed to appropriate.[1] In July 1909, Ricketts proceeded to Mexico to study typhus fever; there, his life was cut short by this disease, which is closely related to Rocky Mountain spotted fever. In 1916, Dr. da Rocha Lima, another pioneer in this field, gave the name *Rickettsia* to those agents that cause the typhus and spotted fever disorders. An independent study conducted by McCalla and Brereton of Boise, Idaho, in 1905, unknown to Ricketts, showed that the bite of a tick removed from one of their patients transmitted spotted fever to two

human subjects—a healthy prisoner and a woman—in whom a moderate and a mild attack of Rocky Mountain spotted fever occurred. This work was not published until 1908.[6]

Wolbach[7] was the first to detail the microscopic lesions of Rocky Mountain spotted fever with descriptions of the classic focal lesions of blood vessels. He distinguished between pathogenic and nonpathogenic organisms in ticks and demonstrated the intranuclear multiplication of rickettsiae in tick tissues.

Much knowledge was added by Spencer and Parker,[8] who showed that guinea pigs could be infected readily by intraperitoneal injection of macerated tick tissue. Ticks obtained in the Bitter Root Valley during early spring failed to cause illness in guinea pigs. Ticks fed on infected goats killed inoculated animals. These workers demonstrated "reactivation" by showing that unfed ticks immunized animals despite their inability to cause demonstrable infection and that virulence could be revived by providing ticks a blood meal (see Section 4). Also, phenolyzed tick juice effectively afforded protection in guinea pigs. Vaccinated humans developed antibodies, and their sera protected guinea pigs from experimental infection. Inactivated infected tick-tissue vaccine for man became a reality.[8]

Cox[9] provided an additional milestone by showing that rickettsiae propagated well in chick-embryo yolk sacs, particularly after death of the embryo. The yolk sac vaccine was simpler to produce and gave fewer reactions.

Therapeutically, immune serum did not prove to be really effective in patients with Rocky Mountain spotted fever. This is principally because rickettsiae are localized intracellularly at the time when the clinical diagnosis becomes apparent, on about the 5th or 6th day. The first effective and specific treatment was para-aminobenzoic acid, which did reduce mortality and morbidity, but it proved awkward to use.[10]

In 1948, first with chloramphenicol and later with the tetracyclines, specific treatment was placed on a firmer basis, and therapy for Rocky Mountain spotted fever became readily available.[11]

It is quite likely that Rocky Mountain spotted fever was prevalent in the eastern Atlantic states before its reported recognition in 1930. Most of the cases in the East probably masqueraded as endemic typhus or were called Brill's disease. Pinkerton and Maxcy[12] reported a case in Charlottesville, VA, that was undoubtedly Rocky Mountain spotted fever. Dyer et al.[13] noted, in 1930, that patients whose illness occurred in the spring and summer along the Eastern Seaboard states closely resembled Rocky Mountain spotted fever. One of these patients was recognized in Maryland by Maurice C. Pincoffs;[14] Dr. Pincoffs's case was published by Dyer et al.[13] In 1901, Sir William Osler diagnosed a patient with typhus at the Johns Hopkins Hospital in Baltimore, MD. The patient died and the autopsy performed by William Henry Welch revealed findings consistent with the emerging pathological characteristics of typhus fever. Ninety years later, the autopsy materials were retested using an immunohistological technique and were clearly demonstrated to contain *R. rickettsi*, proof that Rocky Mountain spotted fever existed in the eastern United States concurrent with its discovery in the West.[15]

3. Methodology

3.1. Sources of Mortality Data

The mortality from Rocky Mountain spotted fever has been variable, especially after the introduction of antibiotics, so that mortality data are not a reliable indicator of incidence. Prior to specific antibiotic usage, the overall mortality rate annually averaged about 20% for all ages. In the mountain and eastern states, where occupational pursuits exposed adults to infected ticks, fatality exceeded 50% in those persons aged 40 or older. It was appreciably lower in children and young adults. Two developments have drastically improved treatment, reduced fatality, and shortened the clinical course of infection. The broad-spectrum antibiotics, first chloramphenicol and later the tetracyclines, were introduced in 1948. When they were given early during the course of Rocky Mountain spotted fever, when the rash was noted, usually on the 3rd–6th day of illness, recovery ensued rapidly. Of equal importance was the elucidation of the pathophysiological abnormalities responsible for the severe manifestations and complications that occur during the 2nd febrile week. Properly applied supportive measures and antibiotic treatment led to recovery in patients who did not come under medical care until late in the illness. Despite these advances in supportive care in managing the late sequelae of late-stage Rocky Mountain spotted fever, a fatal outcome is strongly associated with a delay in diagnosis and therapy.[16,17]

3.2. Sources of Morbidity Data

Rocky Mountain spotted fever is a reportable disease. In patients whose illness is not detected early and treated properly, serious sequelae and a long hospitalization often follow. The Centers for Disease Control and Prevention (CDC) publish the number of cases that occur weekly in various states, previousl under the category of typhus fever ("Tick-borne RMSF"), and now simply as "Rocky Mountain spotted fever". Criteria for diagnosis are somewhat reliable, since

confirmatory serological tests, including the indirect fluorescent antibody (IFA) test or the complement-fixation (CF) reaction, and identification of the *Rickettsia* in skin biopsy by immunohistology are generally available. Some authorities suspect that the data could be confounded by the inclusion of ehrlichiosis and anaplasmosis, or other milder spotted fever group rickettsioses.

3.3. Laboratory Diagnosis

Several types of confirmatory laboratory tests are useful for diagnosis of Rocky Mountain spotted fever: (1) serological tests to detect the presence and increase of specific antibodies in the patient's blood during convalescence;[18] (2) isolation and identification of *R. rickettsii* from blood or tissues; (3) identification of the agent in skin, tissues, or blood by the use of labeled antibodies; and (4) identification of rickettsial nucleic acids in the blood or tissues of infected patients by polymerase chain reaction (PCR) amplification.[19] Since no test is 100% sensitive, a negative laboratory result should not dissuade from institution or continuation of effective therapy. In particular, reliance on serological results during the acute illness is hazardous, and these tests are most useful for confirmation of infection in convalescence. Examination of a peripheral blood smear is not useful for the diagnosis of Rocky Mountain spotted fever.

The CDC defines a confirmed case of Rocky Mountain spotted fever by (1) a fourfold change in antibody titer to *Rickettsia rickettsii* antigen in paired acute and convalescent serum samples, or (2) a positive PCR assay, or (3) immunostaining of antigen in a skin biopsy or autopsy sample, or (4) isolation and culture of *R. rickettsii* from a clinical specimen.[20] The CDC defines laboratory supportive evidence as a clinically compatible case with serologic evidence of elevated lgG or lgM antibody reactive with *R. rickettsii* antigen by IFA, enzyme-linked immunosorbent assay (ELISA), dot-ELISA, or latex agglutination.

3.3.1. Isolation and Identification of *R. rickettsii*. If isolation is attempted, blood should be obtained from the febrile patient prior to antibiotic treatment. Usually, the mononuclear cells are harvested from peripheral blood and used as an inoculum in a centrifugation-assisted shell vial method.[21] Many cell types are susceptible to rickettsial infection, including cells often used in standard virology laboratories, such as Vero cells (African green monkey kidney), L929 mouse fibroblasts, and human embryonal lung (HEL) fibroblast cells, among others. Coupled with the early detection of rickettsial antigen in shell vials by immunofluorescence with species-specific monoclonal antibodies, the diagnosis may be established within as early as 48 h. Isolation in guinea pigs by intraperitoneal inoculation or in chicken embryo yolk sacs is a cumbersome, expensive method rarely used for clinical diagnosis.

3.3.1a. Identification of R. rickettsii *in Tissues.* Immunohistologic techniques, including immunofluorescence and immunoenzymatic methods, are useful for detection of *R. rickettsii* in tissues of patients.[22–24] The most useful specimen is a punch biopsy of a petechial skin lesion. However, the rickettsial infection may be extremely focal, and thus multiple sections must be examined to maximize sensitivity, which averages approximately 70%. The specificity is excellent. Although rickettsia have been observed late after institution of antibiotic therapy, the best opportunity to visualize the organisms by these methods is before initiating treatment, as detection diminishes rapidly thereafter. It must be remembered that a negative result does not exclude Rocky Mountain spotted fever, and thus in suspected cases, therapy should be continued to assure a favorable outcome. The method is useful on both frozen sections and formalin-fixed, paraffin-embedded tissues.[22,25]

3.3.1b. Identification of Rickettsial Nucleic Acids in Clinical Samples. Given the low titer of rickettsiae that are present in peripheral blood of infected patients even at peak rickettsemia, the highly sensitive PCR technique for amplification of rickettsial nucleic acids has been proposed as a specific diagnostic method. PCR can detect DNA in a sample with 5–10 *Rickettsia*. Several target genes can be amplified, including 16S ribosomal RNA, *R. rickettsii* outer-membrane protein (OmpA), a gene encoding the genus-common 17-kDa lipoprotein, and the citrate synthase (*gltA*) gene. The best described is amplification of the 17-kDa antigen gene, and several cases where PCR has allowed a rapid, early diagnosis have been reported.[19] The specificity is dependent on the design of the oligonucleotide primers, but is usually very high. However, the PCR method is no more sensitive than immunohistologic demonstration in skin biopsies,[19] because of the relative lack of rickettsiae in blood at any time. Rickettsial DNA could be best detected in skin biopsies, since the *Rickettsia* are plentiful in sites of vasculitis.[26] DNA amplication is highly specific, but can be confirmed by sequencing to eliminate the possibility of identifying another spotted fever group *Rickettsia*.

3.3.2. Serological Tests. To be useful, serological tests require at minimum two and preferably three serum samples: during the 1st, 2nd, and 4th–6th weeks of illness.[27] Some serological tests such as the latex agglutination and complement-fixation tests are most useful for detection of IgM and for confirmation early after infection and are relatively unavailable now; however, the IFA test, enzyme-linked immunosorbent assay (ELISA), and solid-phase enzyme immunoassay tests (dipsticks)[28] may be useful for detection

of IgG, IgM, or both.[29] Antibodies of the IgG type persist for months to years after the acute infection, and thus tests that detect these immunoglobulins are also useful for seroepidemiological investigations. Typically, a serological diagnosis is rendered when a patient with a consistent illness develops a fourfold rise in antibody titer in convalescence or has a minimum titer that is technique dependent. No serological test has been shown to be highly sensitive during the first 2 weeks of illness, and thus these tests must be considered as confirmatory in convalescence only. No therapeutic decision should be made based on the results of a negative antibody test during acute infection.

3.3.2a. Weil–Felix Reaction. Strains of *Proteus* OX-19 and OX-2 are agglutinated by sera of patients with Rocky Mountain spotted fever. These agglutination tests are now considered to be of historic importance only. The poor sensitivity and very low specificity make these reactions poor predictors of the diagnosis, given the relatively low prevalence of the disease in some geographic regions. Their main advantages are low expense and the ability to test samples under field conditions.

3.3.2b. Indirect Fluorescent Antibody and Microimmunofluorescent Tests (MIF). The standard for rickettsial serological diagnosis is the IFA or MIF test. This test utilizes whole, tissue-culture-propagated rickettsiae, and thus is approximately 99% sensitive.[30,31] In addition, the test has a high degree of specificity for antibodies reactive with spotted fever group rickettsiae; it is rapid and highly sensitive. Some cross-reactivity with typhus group rickettsiae is occasionally seen. Moreover, the test can be used to determine IgG or IgM responses to differentiate recent infection from remote disease. The high sensitivity and ability to distinguish among immunoglobulin classes also makes this test useful for seroepidemiological investigation.

3.3.2c. Other Serological Tests. Because of the lack of a rapid, specific, and sensitive test to replace the outdated Weil–Felix reaction, the latex agglutination test was developed.[32] This serological test uses highly purified rickettsial antigens coated on latex beads, may be rapidly performed within minutes, and is simple to perform and interpret. The test is very sensitive and specific and detects predominantly IgM antibodies useful for early serological confirmation in local hospital and public health laboratories. Another recent addition combines the exquisite sensitivity of enzyme immunoassay methods with the ease of rapid dipstick testing.[28] These tests generally have a high degree of sensitivity and specificity, and some are commercially available.

A recurring problem with the serological diagnosis of species in the genus *Rickettsia* is the lack of specificity to the species level. Thus, with a reactive serological test by any of the above methods, it is impossible to distinguish among agents of the spotted fever group rickettsiae and occasionally it is impossible to exclude typhus group rickettsiae as the causative agent of the disease. The development of a highly sensitive and specific ELISA for Rocky Mountain spotted fever for serological testing, coupled with the use of species-specific monoclonal antibodies that are blocked from attachment by the human antibodies in the test sera, provides a serological tool capable of rendering a diagnosis at the species level.[33] The other serological tests, including the microagglutination test (MA), the indirect hemagglutination test (IHA), and other serological tests such as complement fixation, are no longer used in clinical circumstances.

4. Biological Characteristics of the Organism

R. rickettsii, which possesses the general properties of other rickettsiae, is an obligate intracellular, coccobacillary bacterium. They are minute, averaging 0.6–1.2 μm, and stain purple with Giemsa, light blue with Castenada, red with Machiavello, and bright red with Giménez techniques.[18] These rickettsiae grow in the cytoplasm and nuclei of infected cells of ticks, mammals, and embryonated eggs. Electron micrographs reveal a gram-negative-like cell envelope containing chromosomal material and ribosomes. In some preparations, a microcapsular "slime" layer may be detected. They appear to divide by binary fission.[11,34]

Biochemically, *R. rickettsii* simulate other rickettsiae in chemical composition, metabolic consistency, and nutritional requirements. They contain both RNA and DNA and oxidize certain intermediates of the Krebs cycle.[34,35]

The agent is relatively labile and readily inactivated by heat and chemical agents. Suspensions of infected tissues are inactivated within 24 h by 0.1% formaldehyde or 0.5% phenol. They remain viable for long periods of time when stored at −70°C. When carefully lyophilized from buffered sucrose–glutamate media and stored at 5°C, they remain viable for years.[11]

The antigenic and molecular constituents form the basis for understanding the mechanisms of rickettsial attachment, invasion, and intracellular multiplication. Although *R. rickettsii* has abundant lipopolysaccharide (LPS) demonstrable by chemical and immunoblotting methods, this component contributes little to pathogenesis.[36] In fact, it is likely that the LPS accounts for a large proportion of genus- and group-common antigenicity. By immunoblot analysis, two major immunodominant proteins are evident: a 190-kDa outer-membrane protein (OmpA) and a 120-kDa outer-membrane protein (OmpB).[37] The genes encoding these proteins have been cloned and considerable study has

revealed likely functions for both. OmpA is the putative rickettsial adherence ligand[38] and OmpB functions as both a structural protein and an adhesin.[37,39] Recombinant OmpA has been successfully employed as a protective vaccine in challenged guinea pigs and mice.[40,41] Mutants lacking normal processing of OmpB lack in vitro correlates of virulence.[37]

After rickettsiae attach to a cellular ligand, presumably Ku70 that is induced for surface expression with rickettsial adhesion via OmpB or OmpA,[38,39,42] they gain access to a transiently formed vacuole from which they rapidly escape. Once in the cytoplasm, *R. rickettsii* influences the polymerization of intracellular F-actin, in a manner different from that observed with *Shigella* or *Listeria*.[43–45] This polymerization rapidly mobilizes the organisms and enables cell escape and cell–cell transfer.

R. rickettsii exists in ticks in a nonvirulent form that can be reactivated to a virulent infection-producing phase with a fresh blood meal or when incubated at 37°C for 24 h. This phenomenon probably accounts for the failure of infected ticks, after overwintering, to transmit illness to humans in the early spring until they have attached and fed for at least several hours. Later, during spring and summer, when natural reactivation has presumably occurred, ticks may infect humans after shorter exposure.[11,34]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

The annual number of patients with Rocky Mountain spotted fever in the United States during the years 1950–2005 is shown in Figure 1. For many years, approximately 500 cases occurred annually in the United States; then, after the introduction of specific therapy in 1948, the number of infected cases decreased to a low of about 200 in 1959, 1960, and 1961. This decrease, however, was primarily an artifact of the widespread use of broad-spectrum antibiotics early in the illness, which led to under-reporting and to the use of pesticides.

Beginning in 1969, there was a gradual increase in annual incidence in the United States. There were approximately 900 cases reported in 1975 and 1,067 in 1979.[18,46] Transformation of farms into housing developments and recreation of children and adults in wooded areas probably account for the added exposure to infected ticks, particularly in the southeastern Atlantic states, where the largest number of cases occur. This cyclic pattern has continued as seen in Figure 1. The number of cases has dramatically increased over the last few years and peaked with 2,288 in 2006, more than ever reported before in a single year. A recent seroprevalence study of children living in the southeast and south central regions of the United States found that 12% of children had *R. rickettsia* antibody titers of at least 64 and 4.3% had titers of at least 256,[47] suggesting an even higher prevalence of infection. There is no known explanation for the periodic rise and fall in the number of cases, nor for the marked recent increases (see Figure 1). A similar increase has been recently documented in Brazil and probably other areas of South and Central America.[48,49] Some authorities believe that the recent upward trend reflects increased awareness of tick-transmitted infections, increased diagnostic testing, and detection of antibodies induced by rickettsiae of low pathogenicity.

Rocky Mountain spotted fever in the United States and Sao Paulo typhus in Brazil are the most significant and clinically severe types of the tick-borne group. In the Eastern Hemisphere and elsewhere, the tick-borne rickettsioses are milder and are known variably as fièvre boutonneuse, South African, North Asian, Indian, Siberian, Queensland tick typhus, and others. Mite-borne rickettsialpox with its rodent reservoir is meddlesome rather than important. A large number of other spotted fever group rickettsia have been recently implicated or associated as causes of human disease ranging from mild to fatal.[50]

5.2. Epidemic Behavior and Contagiousness

The epidemiology of Rocky Mountain spotted fever is associated with the biology of the ticks that transmit *R. rickettsii*. Man is entirely an accidental victim and is in no way responsible for the maintenance of the infection in nature, which is due largely to ticks and the animals on which they feed. A number of species of ticks are found infected with *R. rickettsii* in nature. Four species of ixodid ticks have been long recognized as natural carriers of *R. rickettsii*: the Rocky Mountain wood tick, *Dermacentor andersoni*; the American dog tick, *D. variabilis*; the Lone Star tick, *Amblyomma americanum* and the cayenne tick, *Amblyomma cajennense* (in South America); and the rabbit tick, *Haemaphysalis leporispalustris*.[51,52] In 2005 *Rhipicephalus sanguineus,* the brown dog tick was recognized as an important vector in the transmission of *R. rickettsii* to humans in the United States.[53] *D. andersoni* is the principal vector in the West US and *D. variabilis* in the East US. Infected adult female ticks transmit the agent transovarially to many of their offspring. Ticks that become infected, either through the egg or by feeding on an infected mammal at one of the stages during their developmental cycle, harbor the rickettsiae throughout their life span, which may be as long as several years. Usually, cases occur sporadically within an endemic area, although there appears to be an increasing cluster-

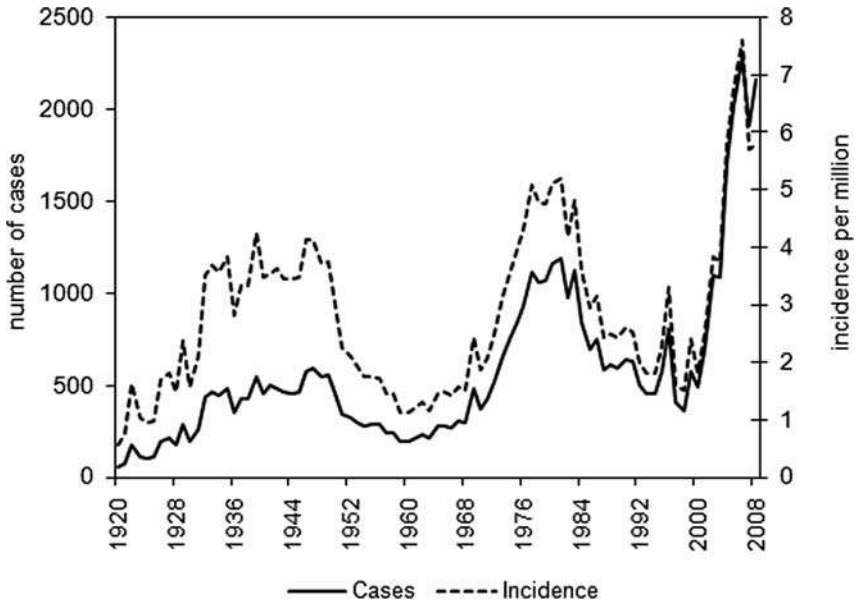

Figure 1. Rocky Mountain spotted fever cases reported in the United States, 1950–2008. Courtesy of the CDC.

ing of patients within families.[54,55] Person-to-person infection does not occur. Thus, the tick probably serves as a reservoir in addition to being a vector. Small animals such as wild mice and other rodents and domestic pets such as puppies may play an important role as reservoirs and in spreading rickettsiae in nature by infecting those new ticks that feed on them during the period of disease when rickettsemia is occurring, but the interval of rickettsemia is usually of limited duration. Most of the natural hosts show only inapparent infections with no overt clinical signs.[11]

5.3. Geographic Distribution

Spotted fever caused by *R. rickettsii* is limited to the Western Hemisphere, largely among wooded areas or fields that are good habitats for natural tick hosts. During the latter 19th century, the first reports were in Idaho and Montana, which led to the name Rocky Mountain spotted fever. The disease has been recognized throughout the United States except in Vermont, probably because of the lower prevalence of the tick vector in these regions. A change in tick vector can alter the distribution of Rocky Mountain spotted fever, as seen in Arizona in 2004 (see Figure 2).[53] It occurs in Canada, Mexico, Panama, Colombia, Argentina, and Brazil and is likely unrecognized in other Central and South American countries. Now, many more cases occur in the East, especially the southeastern and southcentral regions of the U.S., rather than in the West. In contrast, other species in the spotted fever group of *Rickettsia* account for spotted fever disease elsewhere in the world.

5.4. Temporal Distribution

There are seasonal variations in the incidence of cases of Rocky Mountain spotted fever. Most occur during the period of maximal tick activity, usually during the late spring and summer; however, confirmed cases are reported in every month of the year, particularly from the southeastern and south-central states and are particularly infrequent during the winter months in northern states.[11,46]

5.5. Age, Sex, and Occupational Factors

Differences in age and sex distribution of cases relate to exposure to ticks. In the western United States, a relatively higher proportion of adult males contract the disease because of outdoor occupational pursuits, whereas in the East, children and women are infected. This distribution is undoubtedly influenced by occupational propinquity to ticks and is not due to variations in susceptibility of various ages or sexes.[11,46,53]

The age and sex distributions are virtually the same for confirmed and unconfirmed cases. Nearly two-thirds of the cases are in persons less than 15 years of age likely a result of outdoor play exposures and 61% are in males. The case-fatality rates are significantly higher for non-whites (13.9%) than for whites (5.8%), higher for male patients (8.2%) than

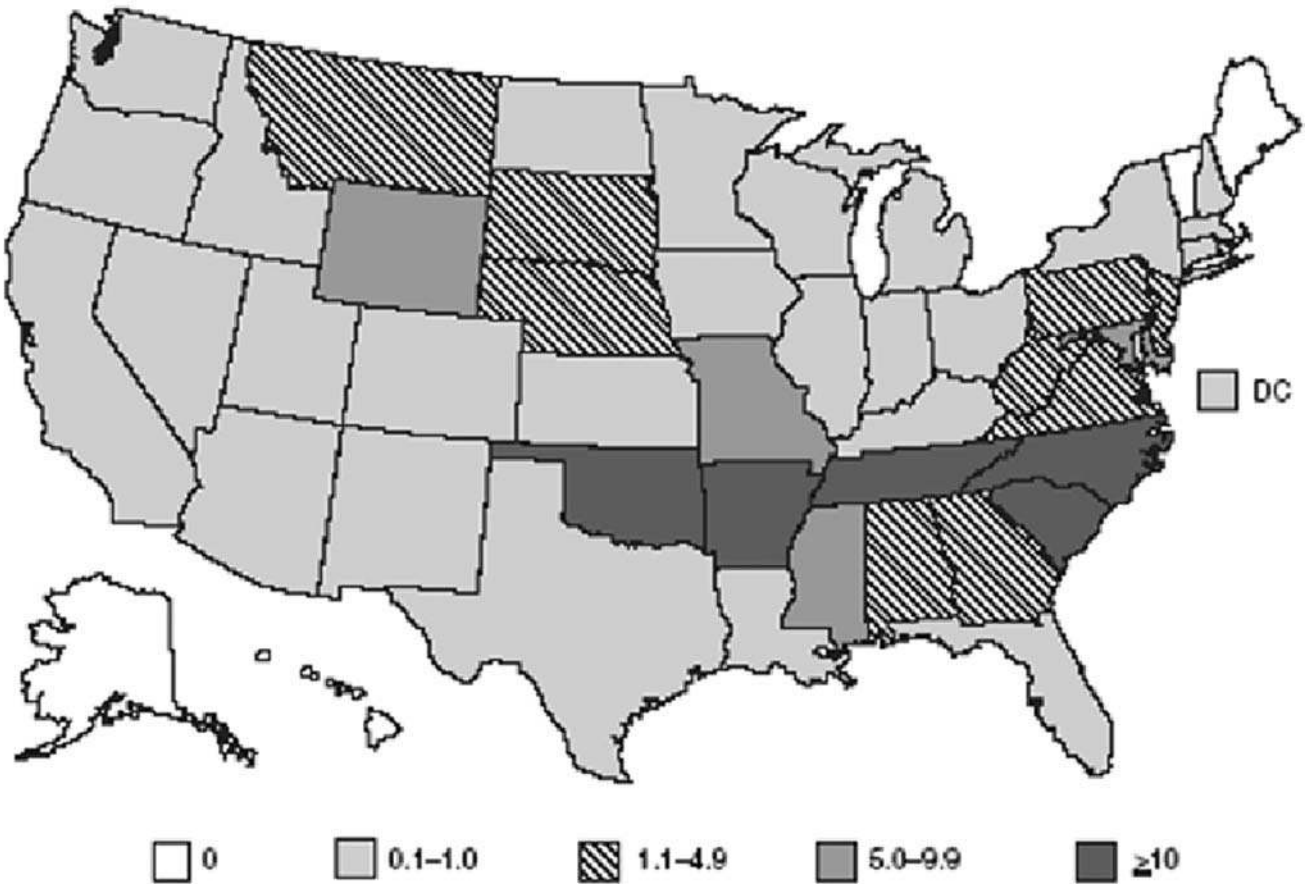

Figure 2. Geographic distribution and incidence (per 1,000,000 persons per year) of Rocky Mountain spotted fever in the United States for 1997–2002. Note the heavy localization in the southeastern and southcentral states.[20]

for female patients (4.5%), and higher for persons older than 30 years (13.9%) than for persons younger than 30 years (5.4%).[46] Delay in diagnosis with absence of an identifiable rash in the dark-skinned patient probably accounts for the variable mortality data.

6. Mechanisms and Routes of Transmission

Man is generally infected by the bite of an infected tick. The need for ticks to "reactivate" their infection from a nonvirulent immunizing phase in unfed adult ticks to a virulent infection-producing phase brought about by the ingestion of fresh blood probably explains why ticks do not cause illness unless they have attached and have fed for several hours. Infection may also be acquired through abrasions in the skin or through mucous membranes that become contaminated with infected tick feces or tissue juices. Hence, there is a hazard associated with crushing ticks between the fingers when removing them from persons or animals.[11] Quantitative studies conducted to test the efficacy of vaccines in volunteers showed that a very small number of viable rickettsiae given intradermally cause illness in man, i.e., 0.1 $GPIPID_{50}$ (50% guinea pig intraperitoneal infectious dose), which is about one rickettsial organism.[56]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Rocky Mountain spotted fever in man follows infection through the skin via tick bite or rarely by respiratory tract with large aerosols after laboratory exposures. The bite of a tick usually transmits *R. rickettsii* after the tick has been attached for several hours. Infection may be acquired through an abrasion in the skin contaminated with infected tick feces or juices. Local lesions (eschars) develop with considerable rapidity at sites of arthropod attachment and initial multiplication of rickettsiae in scrub typhus, the

tick-borne rickettsioses of the Eastern Hemisphere, and rickettsialpox. A primary lesion occurs infrequently at the site of tick attachment in Rocky Mountain spotted fever, although recent observations suggest that a subset of these patients may be infected with another spotted fever group rickettsia such as *R. parkeri*.[26] An eschar also occurs as an initial lesion in tick-borne tularemia, which may confuse the diagnostic picture.[11,57]

After infection, illness occurs within a period varying from 3 to 12 days, the mean being about 7 days. A short incubation period usually indicates a more serious infection. Studies in volunteers have shown that patients with scrub typhus and Q fever have rickettsemia late in the incubation period prior to onset of fever.[58,59]

Similar events probably occur in all rickettsial diseases; circulating rickettsiae can be detected during the early febrile period in practically all patients. Little is known about the pathogenesis of infection during the midportion of the incubation period. Presumably, during this time in patients with Rocky Mountain spotted fever, a transient low-grade rickettsemia results from release of organisms multiplying at the initial site of infection, which then seeds infection within endothelial cells of the vascular tree. The presence of rickettsial antigens and tissue damage elicits an inflammatory response rich in lymphocytes and macrophages, both important components of ensuing cell-mediated immunity. The accumulation of these inflammatory cells at the site of infection leads to the characteristic histopathologic finding of vasculitis. Widespread vascular lesions that develop account for the physical findings such as rash and explain the pathophysiology of the infection as intravascular volume, plasma proteins, and electrolytes are lost into the interstitial spaces.

The exact mechanism by which rickettsiae enter and damage the endothelial cell is not known. *R. rickettsii* binds to an unknown cellular ligand, perhaps surface-expressed Ku70[42] and OmpA or OmpB play critical roles in adhesion.[38,39,42] This binding triggers or is followed by a mechanism that leads to endothelial cell invasion. Initially this process is mediated by phagocytosis associated with changes in intracellular calcium and the presence of phospholipase activity,[60,61] presumably of rickettsial origin since a phospholipase D-like gene encoding phospholipase activity is present in its genome.[62] Similarly, *R. prowazekii* contains a putative hemolyin, encoded in *tlyC*, that together with rickettsial Pld damages host cell membranes and may serve roles in (1) induced phagocytosis as a host-mediated reparative process and (2) escape from the phagosome into the cytoplasmic compartment before phagosome–lysosome fusion occurs.[62,63] Once within the endothelial cell, the rickettsiae mediate F-actin polymerization and become actively mobile.[43–45] The rickettsiae multiply by binary fission, and via actin polymerization the rickettsiae escape the cell, often prior to any evident cell injury. In most cases, endothelial cell damage is irreversible, and ultrastructural and biochemical evidence point to free radical and oxidative membrane injury.[64–66]

Later in the course of illness, the cascade of immune events is activated and matures. The macrophages attracted to the focus of infection undoubtedly process and present rickettsial antigens to T lymphocytes and secrete important cytokine mediators of inflammation including tumor necrosis factor-α and interferon-γ.[67] Data from animal models and in vitro studies suggest that cytokines such as tumor necrosis factor-α and interferon-γ act on infected cells to result in cell destruction and death of the rickettsiae contained within.[68] Cytokine-mediated alterations or damage coupled with rickettsia-mediated injury to critical endothelial cells compromises not only vascular flow but also enhances procoagulant activities, clinically resulting in thromboses or abnormalities in coagulation.[69] The activation of T lymphocytes, especially natural killer cells, leads to local secretion of interferon-γ, perhaps the most important cytokine factor elaborated by immune cells for enhancing intracellular rickettsial killing and protective immunity.[70,71] The balance of the degree of host injury (mediated by both the rickettsiae and host cytokines) and the degree to which rickettsiae are eliminated (via specific immune and nonimmune mechanisms) determines the overall amount of endothelial cell and vascular injury and is likely to be directly related to the clinicopathological findings and course in any given patient. This cellular and molecular pathogenetic sequence is consistent with in vitro experiments, animal models, and the experiences gleaned from human disease. In patients, infection is associated with induction of cutaneous delayed-type hypersensitivity reactions,[72] lymphocyte transformation,[73] and the development of serum antibody. However, antibody clearly lacks a protective effect and is unable to reverse an established infection although its contribution to protection against reinfection is now being re-evaluated.[30] The use of corticosteroids has some beneficial effect in human disease, probably by diminishing local inflammation and suppressing additional cytokine-mediated effects. When used in animal models, corticosteroids do not prevent death. Overall, it appears that induction of inflammation and immunity is beneficial to the infected human host, since the major goal is the elimination of the spread of intracellular infection by sacrificing the large numbers of infected endothelial cells and perhaps some critical vascular beds. When severe vasculitis is present, later in the illness, there is increased capillary permeability and vascular leakage that expands the extravascular space. This can lead to leakage of fluid into the lungs, brain, and peripheral tissues, particularly when excess fluids are administered intravenously.

7.2. Immunity

Second attacks of Rocky Mountain spotted fever have not been reported, although relapse infection after several days to weeks has developed in patients treated with antibiotics very early in illness. These are really continuing infections and not true recurrences.[56] A recurrent type of Rocky Mountain spotted fever such as Brill–Zinnser epidemic louse-borne type has not been reported. Clinicians should be alert to this possibility. Studies of cross-immunity in susceptible animals show protection among the various rickettsiae of the tick-borne group and rickettsialpox. Always, the protection derived from homologous antigens is more significant.

The underlying protective effectors after recovery from natural infection are not precisely identified; however, it is clear from in vitro and in in vivo experiments that natural killer cells and their secretion of interferon-γ play a critical role.[71] Infection and illness has been elicited in patients with high levels of preexisting antibody and preexisting in vitro correlates (lymphocyte transformation) of cell-mediated immunity.[73] The specific host and rickettsial factors that influence the development of an acquired protective immune state are actively being sought.

8. Patterns of Host Response

8.1. Common Clinical Features

A history of tick bite is elicited in approximately 58–80% of patients.[11,46,57] The onset of illness is usually abrupt with severe headache, a shaking chill, prostration, generalized myalgia, especially in the back and leg muscles,[11] nausea with occasional vomiting, and fever that reaches 102–104°F within the first several days. In some, the infection can be mild, accompanied by lethargy, anorexia, headache, and low-grade fever. These symptoms are similar to those of many infectious diseases and make specific diagnosis difficult during the first several days. Since *R. rickettsii* has only been isolated from humans with significant diseases, it is doubtful that many human inapparent infections occur, although seroprevalence data suggest otherwise.[47] However, the recognition of infections by *R. parkeri* that are mild and result in a seroconversion to *R. rickettsii* provides a potential explanation for high seroprevalence.[26]

8.1.1. Fever. In severe cases, fever continues for approximately 15–20 days; the febrile course in children may be shorter. Usually, the fever maintains a high continuous course with morning remissions that do not reach normal. Hyperpyrexia of 105°F or greater is usually an unfavorable sign, although death may occur when the patient is hypopyrexic with associated vasomotor collapse. Defervescence usually occurs over several days. Recurrent fever is unusual except in the presence of pyogenic complications.

8.1.2. Headache. Headache is usually general and severe, with frontal intensity. It persists during the 1st and 2nd weeks of illness in untreated cases; occasionally, it is mild. Malaise and muscle pain continue during the 1st week. Irritability is common, and the patient is often distracted during questioning and examination.

8.1.3. Rash. One of the most characteristic and helpful diagnostic signs is the rash, which usually appears on the 4th febrile day; the range is 2–6 days. Initial lesions are on the wrists, ankles, soles, palms, and forearms. They are macular, pink, and irregularly defined, and measure 2–6 mm (Figure 3). A warm compress on the extremities may accentuate a faint rash, and the rash is more prominent with elevated temperature. After about 12–24 h, the rash extends centrally to the legs, buttocks, arms, axillae, trunk, neck, and face. In epidemic typhus fever, the rash spreads from the trunk to the extremities. In about 2–3 days, the rash becomes maculopapular and assumes a deeper red hue (Figure 3). After 4 days or so, the rash is petechial and fails to fade on pressure (Figure 3). Often, the hemorrhagic lesions coalesce to form large ecchymoses (Figure 3). These lesions often form over bony prominences and may slough to form indolent, slow-healing ulcers. In convalescence, the petechiae fade to form hyperpigmented discolorations for several weeks. In mild cases, the rash does not become petechial or purpuric and may disappear within several days. Antibiotic treatment may abort the early exanthem; the late fixed lesions fade slowly with specific therapy. In some patients, particularly those with dark skin, a rash does not occur or is unnoticed. When tourniquets are applied to the extremities for several minutes or when the blood pressure is taken, additional petechiae may appear (Rumpel–Leade phenomenon); this is further evidence of capillary abnormalities. Photophobia and redness of the peripheral conjunctivae are often present.

8.1.4. Cardiovascular and Respiratory Signs. In severe cases, the pulse is rapid and the blood pressure is low. Circulatory failure with shock is an ominous sign and is an indication of the peripheral vascular atonicity and collapse. Ecchymotic skin lesions, cyanosis, and gangrene of the fingers, toes, genitalia, and buttocks are all unfavorable signs. The electrocardiogram shows changes indicative of myocardial involvement, and arrhythmias of various types indicate myocarditis, which may lead to cardiac arrest and death. In severely ill patients, edema of the arms, legs, and face indicates vascular decompensation and capillary abnormalities.

Figure 3. Evolution of skin rash in RMSF. Most physicians are educated to believe that the predominant rash of RMSF is petechial; however, a spectrum of findings is more typical, ranging from early macular or maculopapular (*top left*) rashes to petechial (*top right* and *middle left*) or purpuric lesions with advanced stages or fatal RMSF (*bottom*, courtesy Grover Hutchins, M.D.). *Rickettsia rickettsii* can be demonstrated in endothelium of dermal vasculitic lesions by immunohistochemistry (*middle right*). From Dumler and Walker, *N Engl J Med*, 2005; 353: 587–594 (Copyright © 2005 Massachusetts Medical Society. All rights reserved. Bottom panel with permission from G. Hutchins, M.D.).

Respiration is usually rapid, and a nonproductive cough with pulmonary rales is indicative of a form of rickettsial pneumonitis. Lung consolidation is rare. Judicious use of intravenous fluids is warrantred as they may provoke pulmonary edema.

8.1.5. Hepatic and Renal Signs. Hepatomegaly occurs; usually, there is no jaundice. Hypoalbuminemia results from leakage of albumin into subcutaneous tissues and abnormal hepatic function. Oliguria, anuria, and azotemia are indicators of vascular decompensation and renal involvement. Acute renal failure is highly associated with mortality.[17]

8.1.6. Gastrointestinal Signs. Abdominal distension is frequent and occasionally some degree of intestinal ileus is observed. Constipation is usual. More acute manifestations with abdominal pain may suggest the presence of either appendicitis or cholecystitis.

8.1.7. Neurological Signs. Headache, restlessness, insomnia, and back stiffness are common neurological manifestations. Coma, muscular rigidity, athetoid movements, convulsive seizures, and hemiplegia (rare) are grave signs and indicate the presence of encephalitis. Deafness during the acute illness and in convalescence is common. Most of the CNS signs abate with time.

8.2. Clinical Course and Complications

In mild and moderately severe cases, the illness abates in about 2 weeks. Convalescence is rapid. If death occurs, it is usually during the latter part of the 2nd week as a result of toxemia, vasomotor weakness, and shock or renal failure with azotemia. In a few patients, the course is rapidly fulminant with death outdistancing treatment, occurring as early as the 6th day of illness.[11,46]

The most significant complication comes from delayed diagnosis of RMSF.[17,20] Even in areas with a higher than average prevalence, where physicians' awareness of the illness is increased, the diagnosis of RMSF is often delayed and the standard therapy for pediatric patients is not always given.[74] Delayed diagnosis and treatment affects outcome and increases mobidity and mortality.

8.3. Diagnosis

During the early stages of infection before the rash has appeared, differentiation from other acute infections is difficult. History of tick bite while living or traveling in a highly endemic area is helpful.

Cutaneous manifestations can be used to help distinguish Rocky Mountain spotted fever from other febrile exanthems. The rash of meningococcemia resembles that of Rocky Mountain spotted fever in certain aspects, since it is macular, maculopapular, or petechial in the chronic form, and petechial, confluent, or ecchymotic in the fulminant

type. The meningococcal skin lesion is tender and develops with extreme rapidity in the fulminant form, whereas the rickettsial rash occurs on about the 4th day of disease and gradually becomes petechial. High blood leukocyte counts are common in meningococcal infections. The exanthem of rubella rapidly becomes confluent, while that of rubeola almost never becomes petechial. The exanthem of varicella or variola is first erythematous and later becomes vesicular. The rose spots of typhoid fever are usually on the lower chest or abdomen and remain delicate, without hemorrhagic character. Rocky Mountain spotted fever skin lesions, in contrast to those of typhoid, begin on the periphery of the skin and later become petechial. The rash of infectious mononucleosis is usually morbilliform on the trunk and rarely becomes petechial. Lymphadenopathy and atypical lymphocytes in the blood are differentiating features. Murine typhus and cat flea typhus (caused by *Rickettsia felis*) are milder than Rocky Mountain spotted fever; the rash is less extensive and is usually nonpurpuric and nonconfluent; renal and vascular complications are uncommon. Not infrequently, differentiation of these two rickettsial infections must await the results of specific serological tests. Epidemic typhus fever is capable of causing all the pronounced clinical, physiological, and anatomical alterations seen in cases of Rocky Mountain spotted fever, i.e., hypotension, peripheral vascular failure, cyanosis and gangrene of digits, renal failure with azotemia, and neurological manifestations. However, the rash of classic typhus is noted initially in the axillary folds and on the trunk and later extends peripherally, rarely involving the palms, soles, or face. The serological patterns in these two diseases are distinctive when specific rickettsial antigens are employed in tests. Moreover, louse-borne typhus is not recognized in the United States except in the form of Brill–Zinsser disease (recurrent typhus fever) and the rare cases associated with flying squirrels (sylvatic typhus). Rickettsialpox, and now *R. parkeri* infection, although both caused by members of the spotted fever group, are usually readily differentiated from Rocky Mountain spotted fever by the initial lesion, the relative mildness of the illness, and with rickettsialpox, the early vesiculation of the maculopapular rash.

The laboratory findings in Rocky Mountain spotted fever are nonspecific. However, several features may aid in establishing the differential diagnosis. Rocky Mountain spotted fever is often associated with normal or low leukocyte counts and significant left-shifts in patients who are quite obviously ill and would be expected to have leukocytosis. Platelet counts are frequently diminished. Careful evaluation of coagulation tests may reveal mild abnormalities, and despite the occasional clinical appearance of a state suggestive of disseminated intravascular coagulation, fibrinogen levels in serum are usually within normal ranges. Electrolyte abnormalities occur often, particularly hyponatremia, and these are best explained on the basis of appropriate antidiuretic hormone release in response to the loss of intravascular volume into interstitial spaces and by the actual redistribution of electrolytes into third space tissue compartments. Elevations in serum hepatic transaminases, creatine phosphokinase, lactate dehydrogenase, and other enzymes are likely to result from bystander inflammatory injury to hepatocytes or injury secondary to ischemia and hypoperfusion. The development of hyperbilirubinemia and hepatic failure is an ominous sign indicative of severe, probably impending fatal infection. Abnormalities in urea nitrogen and creatinine levels usually indicate renal injury secondary to hypovolemia; however, rickettsial interstitial nephritis is well recognized and may be a contributor in some circumstances. Careful intrepretation of laboratory findings and correlation with the clinical examination are imperative. Most often, the clinical findings and laboratory examination will reveal evidence of a systemic disease, findings that will discourage unwarranted surgical interventions.

Scrub typhus, African tick-bite fever, and boutonneuse fever (Mediterranean spotted fever) patients are being increasingly reported in the United States among travelers from the Far East[75] and Africa.[76,77] The clinical features may simulate Rocky Mountain spotted fever when severe, especially for scrub typhus and boutonneuse fever; however, when detected early, antibiotic treatment is very effective. The vector of scrub typhus is a mite and ticks are the vectors of African tick-bite and boutonneuse fevers.

9. Control and Prevention

9.1. Vector Control

Avoiding or reducing the chance of contact in tick-infested areas of known endemicity is the principal preventive measure. When this is impractical, area control of ticks may include the following prophylactic measures:

1. Spraying the ground with acaricides for tick control. Although there are environmental objections to the use of residual insecticides, such procedures may be warranted under special conditions.
2. Application of repellents such as N, N-diethyl-m-toluamide (DEET) or dimethyl phthalate to clothing and exposed parts of the body, or in very heavily infected areas, the wearing of clothing that interferes with the attachment of ticks, i.e., boots and a one-piece outer garment preferably impregnated with repellent.[11]
3. Daily inspection of the entire body, particularly of children, including the hairy parts, to detect and remove attached ticks. Care should be taken in removing attached ticks to avoid crushing the arthropod, which will contaminate the bite wound. Gentle traction

with small forceps applied close to the mouth parts allows ready extraction.[78] The skin area should be disinfected with soap and water or other antiseptics such as alcohol. These precautions should be employed in removing engorged ticks from dogs and other animals because infection through minor abrasions in the hands is possible.

9.2. Chemotherapy and Prophylaxis

The question is often raised whether antibiotics should be given prophylactically after human exposure to virulent *R. rickettsii*. In guinea pigs, a single dose of oxytetracycline prevented the disease when the antibiotic was given shortly before expected onset. However, relapses occurred when treatment preceded expected onset by 48 h or more.[79] This regimen is not recommended. After a tick bite in a known endemic area, an exposed person should be observed for signs of fever, headache, prostration, and rash; therapy is very effective at the early stage of illness.

Tetracycline (doxycycline) is specifically effective for treatment of Rocky Mountain spotted fever. It is rickettsiostatic, not rickettsicidal. Clinical manifestations subside promptly, if initiated early when the rash first appears. Doxcycline is preferred over tetracycline since it is associated with lower tooth discoloration and less frequent dosing, significantly reducing concern over treatment in children less than 8 years. Historically, chloramphenicol has also been considered effective, although this is now a controversial point.[80,81] While some in vitro studies have suggested the possibility that fluoroquinolones and macrolides could be useful treatments for RMSF, no clinical trials to determine efficacy in vivo have been conducted. Any seriously ill child or adult who lives in a wooded area with unexplained fever, headache, and prostration, with or without a history of tick contact should be suspected of having Rocky Mountain spotted fever. Specific treatment should be initiated after blood is taken for diagnostic tests. Optimal antibiotic regimens include twice daily doxycycline 100 mg (adult dose) or 2.2 mg/kg (child dose) orally or by intravenous injection. Therapy is continued until the patient has improved and has been afebrile for about 48 h. Intravenous preparations are used in patients too ill to take oral medications.

Although not supported by any clinical trials, critically ill patients first observed late in the course of illness may be given large doses of corticosteroids (for treatment of the vasculitis) in combination with specific antibiotics for about 3 days. Such patients often show circulatory collapse, oliguria, anuria, azotemia, hyponatremia, hypochloremia, edema, and coma. In such patients who manifest increased capillary permeability, intravenous fluids should be given cautiously to avoid increasing pulmonary and cerebral edema. In mildly or moderately ill patients, these pathophysiological abnormalities are not present.

9.3. Immunization

Spencer and Parker[8] were aware that infected ticks, when they first come out of hibernation, produce either no or low-grade infections in guinea pigs. They found that one infected egg from an infected female tick when triturated and inoculated into a guinea pig produced spotted fever and that suspensions of infected ticks treated with phenol protected guinea pigs against virulent challenge. Spencer and Parker[8,82,83] tested the new vaccine on themselves and showed that a sample of their blood, taken after vaccination, mixed with virulent rickettsiae protected guinea pigs against infection. They developed a tick-derived vaccine, inactivated and preserved with 1.6% phenol and 0.4% formalin. The vaccine was difficult to produce and expensive, originally costing $20.00 per injection. Studies of efficacy were carried out over a number of years. Although no carefully controlled experimental trials were conducted, it appeared, on the basis of differences of attack rates in small groups of vaccinees and control volunteers, that the vaccine prevented the mild type of spotted fever and sharply reduced the mortality in the highly fatal type.[84] The vaccine was moderately reactive, producing malaise, nausea, slight fever, arthralgia, myalgia, and serum sickness in about 1% of recipients.

Cox developed an inactivated vaccine prepared from rickettsiae grown in yolk sacs of fertile hens' eggs. This was the standard preparation for a number of years.[85] Immunization consisted of a course of three injections of 1.0 ml each given subcutaneously at weekly intervals. Vaccination was preferably performed in the spring before the advent of the spotted fever season, and a 1.0-ml stimulating dose was recommended each year for those at risk. There was little reaction from the vaccine. This chick-tissue vaccine produced commercially (Lederle) was not conclusively tested in the field, and furthermore, the relationship between the immunity demonstrated in guinea pigs and that induced in man following administration of vaccine was inconclusive.

A quantitative trial of inactivated vaccines made from infected tissue and embryonated hens' eggs was conducted in volunteers followed by a challenge with virulent (viable) *R. rickettsii*.[56] Humoral antibodies appeared in a low percentage of vaccinees after use of either available vaccine. It was noted in the vaccinated group that when they were injected with a few virulent rickettsiae 3–6 months after a full course of vaccination, the incubation period was prolonged and the frequency of early clinical relapse was lessened.

Vaccinated volunteers were not protected (when compared with controls) against development of clinical illness. In vaccinees, the clinical illness appeared to be shortened,[56] which coincided with the earlier findings of Parker.

There was great hope that a cell-culture-derived, inactivated *R. rickettsii* vaccine would provide greater protective effect than the previously approved vaccines. Initial studies in nonhuman primates suggested efficacy; however, when administered to humans as a challenge trial, the results were disappointing.[72] No vaccinated volunteer was protected from illness, despite induction of serum antibody and in vitro correlates of cell-mediated immunity.[73] The interpretation of all the studies suggests that the vaccine might be useful if the regimen were modified to include more rickettsial mass and more booster immunizations.

To date no proven or approved vaccine for Rocky Mountain spotted fever exists. Research designed to investigate the important rickettsial factors toward which protective immune responses may be directed is in progress. The successful elucidation of Omps and perhaps Pld as targets for human vaccine development using recombinant proteins has revealed promising results in animal models.[41,62,86] A clearer understanding of the mechanisms by which intracellular infections are resolved and protective immunity is established is mandatory before another human vaccine can be proposed. Until then, the need will not diminish, but other methods for control will be required.

10. Unresolved Problems

Specific chemotherapy of the rickettsial diseases was achieved in 1948. This event inadvertently diverted attention from pursuit of studies aimed at elucidating pathogenesis, pathophysiological abnormalities, and control by vaccines. Some unanswered puzzles awaiting solution are

1. What is the nature of the increased capillary permeability and the cause of the characteristic vascular lesion? The specific molecular events leading to *Rickettsia*-mediated host membrane damage and the relative contributions of host-derived "pathological" cytokine responses and their reversal need clarification. There are favorable advances in understanding control of illness mediated by the untoward effects of cytokines. Are the changes a result of direct effects by rickettsiae within endothelial cells, an action of their manipulation of cellular signaling processes, a combination of both, or an immunopathologic reaction? Evidence does not permit the exclusion of any one mechanism.
2. Hematologic findings in severely ill patients with spotted fever and typhus show a disseminated intravascular coagulation defect late in illness. Its mechanism and the relationships of complement abnormalities merit study.
3. Therapy for early cases is simple and effective. For seriously ill patients during later stages, there is a need for better antitoxemic measures, which will evolve only when the nature of the pathological lesions and the toxic manifestations are understood. Short-term high-dose steroid treatment for several days combined with antibiotics is helpful and is unassociated with sequelae.
4. Spotted fever and typhus group rickettsiae persist within human cells, presumably within macrophages; Brill–Zinsser disease is a recurrence of epidemic typhus years after the initial infection. This is a remarkable example of microbial persistence. Conceivably, there is a Brill–Zinsser pattern for other rickettsial diseases such as spotted fever, murine and scrub typhus, and Q fever. An understanding of the intracellular growth requirements might provide leads to the complete inactivation of rickettsiae. An important lead will be the cultivation of rickettsiae on artificial media.
5. There is a need for better biological vaccines for prevention of typhus, spotted fever, and Q fever. Inactivated Q fever vaccine is effective but causes reaction on repeated inoculation. A tissue-culture-derived inactivated vaccine for spotted fever is under development and appears promising. This system may be useful for production of better epidemic typhus vaccines. Live strain E vaccine for typhus is effective but reactive, and reversion to virulence has been reported.[87] There are no effective vaccines for scrub typhus. Whether the threat of some rickettsial diseases for humans warrants research directed toward developing attenuated viable vaccines should be carefully considered.
6. The interrelationships of rickettsiae in animal hosts, vectors, and other environmental factors for epidemic and murine typhus, Rocky Mountain spotted fever, and Q fever are really under-developed. For example, there may be a significant reservoir of *R. prowazekii* other than man, such as flying squirrels. Fleas or lice may serve as vectors.
7. Better systems are needed for genetic modification of rickettsia to either inactivate rickettsial genes or transfer mutant genes into rickettsiae. This would allow a modern molecular equivalent of Koch's postulates to be applied for the understanding of rickettsial molecular and cellular pathogenesis.

Current work by several investigators is directed to these questions.

CHAPTER 32

Salmonellosis: Nontyphoidal

Michael F. Lynch and Robert V. Tauxe

1. Introduction

Nontyphoidal salmonellosis traditionally refers to disease caused by any serotype of organisms in the genus *Salmonella*, other than *Salmonella* Typhi, the causative agent of typhoid fever (see Chapter 42). The most common manifestation of nontyphoidal salmonellosis is acute enterocolitis, but the organism can cause focal infection, bacteremia, meningitis, as well as "enteric fever" that may be clinically indistinguishable from that caused by *S.* Typhi. Nontyphoidal salmonellosis is a disease of considerable clinical and public health importance. An estimated 1.4 million cases of salmonellosis occur each year in the United States, of which a small fraction are cultured and reported. The direct patient care and lost productivity costs alone have been estimated to exceed $2 billion annually, but when one considers the added costs of plant closings, product recalls, and losses of food production, the true economic impact of salmonellosis is likely to be substantially greater.[1]

Over 2,000 serotypes of *Salmonella* have been described.[2] The nomenclature of *Salmonella* has undergone considerable evolution over recent years, which has led to some confusion. By DNA hybridization, two species, *Salmonella enterica* and *Salmonella bongori*, have been identified.[2] Almost all clinical *Salmonella* isolates belong to *S. enterica,* which is further subdivided into six subspecies. Most *Salmonella* serotypes associated with human diseases belong to subspecies 1 (subspecies *enterica*), but strains in subspecies 3, once referred to as the Arizona group, are occasionally isolated. Previously, the genus *Salmonella* was classified into three primary species which were called *Salmonella typhi*, *Salmonella cholerae-suis*, and *Salmonella enteritidis*; Arizona organisms were in a separate genus. The species *S. typhi* and *S. cholerae-suis* consisted of a single serotype each; the remaining 2,000 serotypes were in the species *S. enteritidis*. The formal designation of a serotype is *S. enterica* subspecies *enterica* serotype Typhimurium or *S. enterica* subspecies *enterica* serotype Enteritidis.

To avoid the awkwardness present in this and previous nomenclatures, we will designate each serotype directly, without reference to the full species name. Thus, *S. enterica* subspecies *enterica* serotype Typhimurium is written *S.* Typhimurium and *S. enterica* subspecies *enterica* serotype Enteritidis is written *S.* Enteritidis. Serotypes outside of subspecies 1 are now referred to by their antigenic formulae. The two different organisms formerly known as *Salmonella* Paratyphi B and *Salmonella* Java actually share the same serotype, but are distinguished by the tartrate test; they are now referred to explicitly as tartrate-positive or -negative variants of *S.* Paratyphi B.

Salmonellae probably evolved with the reptiles and birds and are well adapted to a variety of host animals. The diversity of serotypes reflects this diversity of hosts, as many serotypes have a narrow host range. For example, clinically important infections due to *S.* Typhi occur only in humans, and humans are the only known reservoir for this organism. The primary reservoir of *Salmonella* Gallinarum and *Salmonella* Heidelberg is chickens; the reservoir of *Salmonella* Choleraesuis is pigs; for *Salmonella* Bovismorbificans it is cows; IV 50:g,z51: (*Salmonella* Marina) is the marine iguana; and Paratyphi B var. L(+) tartrate+ (*S*. Java), *S*. Urbana, and *S*. Litchfield are predominantly turtle associated. Nonetheless, all serotypes should be considered potentially pathogenic for humans and animals. In addition to distinctive host ranges, many serotypes exhibit unique patterns of virulence, antibiotic resistance,

and geographic distribution that make the epidemiology of *Salmonella* particularly fascinating and complex.[3]

2. Historical Background

Salmon and Smith[4] reported the isolation of "hog cholera bacillus," later named *S.* Choleraesuis, from diarrheic swine in 1885. Three years later, Gaertner[5] reported the first foodborne outbreak of nontyphoidal salmonellosis, in which 58 persons fell ill after eating raw meat from an ill cow; "Gaertner's bacillus," later named *S.* Enteritidis, was isolated from the meat, and from the spleen of a man who died in the outbreak. In 1889, Loeffler isolated *S.* Typhimurium during an outbreak of diarrheal illness in a laboratory mouse colony; the same organism was demonstrated among victims of a meat-associated outbreak in Aertrycke, Belgium, in 1899.[6,7] By the turn of the century, the pathogenic potential of *Salmonella* for humans was widely appreciated in Europe, and following World War I, salmonellosis emerged as a common public health problem on that continent. Between 1923 and 1938, 374 outbreaks due to 11 different serotypes of nontyphoidal salmonellae were reported in the United Kingdom.[6] *Salmonella* Enteritidis infections associated with duck eggs became common in Europe and led to the decline in popularity of this food before World War II.[8] In 1941, Kauffmann[6] presented an expanded version of White's approach to the great antigenic diversity of *Salmonella*. The Kauffmann–White schema defined the antigenic formula of each serotype, and provided the widely used nomenclature that we have followed here.

In the United States, nontyphoidal salmonellosis did not emerge as a public health problem until after World War II. The number of reported clinical cases increased from 502 in 1942, the first year that the condition was made nationally reportable, to 65,347 in 1985 (the year of a large milk-associated outbreak) and declined to 45,322 in 2005 (Figure 1). Over the same time, typhoid fever, caused by *S.* Typhi, became rare. In 1962, following a large multistate outbreak of egg-associated *Salmonella* Derby infections, a second national surveillance system for *Salmonella* was instituted, based on reports of laboratory isolates, which include serotype. This surveillance system, coupled with intensive epidemiological investigations, has helped to clarify our understanding of the complex routes of *Salmonella* transmission. As a result of this improved understanding, specific control measures have been implemented. The rapid rise in reported incidence of salmonellosis in the 1970s and 1980s, slight decline in the 1990s and stable rates in the first few years of the 21st century, indicates the need for further improvements in our efforts to control this pathogen of the modern era.

3. Methodology

3.1. Sources of Mortality Data

Data are limited on the mortality from salmonellosis in the United States. Deaths due to salmonellosis are not routinely reported to the Centers for Disease Control and Prevention (CDC) national surveillance systems. Mortality can be estimated from periodic nationwide surveys of sentinel counties and established active surveillance in sentinel sites (see Section 3.3), from death certificates, and from outbreak investigations. The surveys of sentinel counties and active surveillance in sentinel sites probably give the most reliable overall estimate of mortality. The sentinel county studies yielded a mortality rate of between 0.5 and 1.4%, which is similar to that found in 16 years of surveillance in Massachusetts,[9] but lower than the 4.1% mortality rate observed in New York between 1939 and 1955.[10] More recently, a mortality rate of 0.6% was estimated from active surveillance in five sentinel sites for the years 1996–1999, accounting for an estimated 400 deaths due to salmonellosis annually in the United States.[11] In outbreaks, the typical case-fatality rate is 0.1% of affected persons.[12] This is lower than the mortality for reported cases because outbreak investigations identify many milder cases that would not be cultured, diagnosed, or reported had they occurred as sporadic cases. Approximately 20–40 deaths per year due to salmonellosis are identified from death certificate data.[13] Death certificates may not reflect the bacteriologic diagnosis in patients dying of gastroenteritis, dehydration, sepsis, or meningitis if appropriate cultures are not obtained or culture results are not available at the time of death. Deaths due to *Salmonella* may be hidden in those attributed to septicemia, meningitis, or cardiopulmonary arrest.

3.2. Sources of Morbidity Data

Since 1962, the laboratory-based National *Salmonella* Surveillance Program has been conducted by the CDC working jointly with the Council of State and Territorial Epidemiologists, the Association of State and Territorial Public Health Laboratory Directors, the US Department of Agriculture, and the US Food and Drug Administration. This program is based on weekly reports of *Salmonella* isolations from the states and from the District of Columbia, and

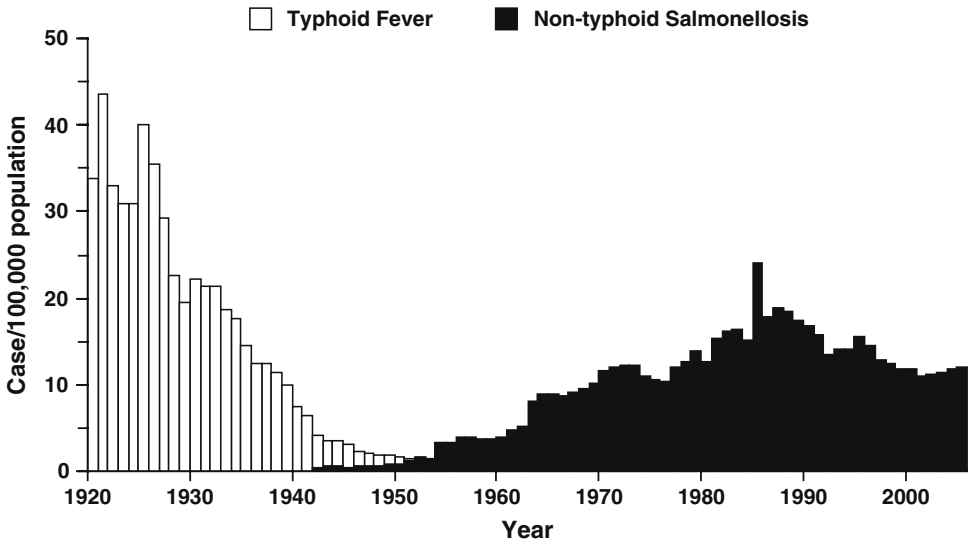

Figure 1. Reported incidence of clinical typhoid fever and nontyphoid salmonellosis in the United States from 1920 to 2005. Data from CDC [13] (1985 peak of nontyphoidal salmonellosis includes cases from massive outbreak with >16,000 culture-confirmed infections.[38]).

regular summaries of nonhuman isolates from the Food and Drug Administration and the US Department of Agriculture. All laboratories are requested to forward clinical isolates of *Salmonella* to the state or regional laboratory for serotyping, and the results are reported along with information on sex, age, county of residence, and site of isolation. Since 1993, these data are transmitted, collected and analyzed electronically via the Public Health Laboratory Information System (PHLIS).[14] The purpose of this laboratory-based surveillance program is to define patterns of endemic salmonellosis in the United States, to identify trends in disease transmission, and to monitor control efforts. The predecessor to this system, based on physicians' reports of cases, began in 1942 when nontyphoidal salmonellosis became a notifiable disease, and continues to function in parallel. The clinical case-reporting system yields comparable numbers of cases, but because case definitions vary from state to state and the reports do not include serotype, it is of limited epidemiological use.

Limitations and biases exist in the laboratory-based data as well. The reports do not discriminate between symptomatic and asymptomatic cases, and cases of salmonellosis without laboratory confirmation are not included. Several factors influence whether a case of salmonellosis will be reported to the *Salmonella* surveillance system, including the following: the severity of illness, access to medical care, and the association with a recognized outbreak. Physicians may be more likely to obtain stool cultures from infants and elderly persons with gastroenteritis than from young adults, and illness in these age groups may be oversampled. By comparing the number of cases detected in outbreak investigations with the number of outbreak-related cases that are reported to the *Salmonella* surveillance system, it is possible to estimate the sensitivity of the system. Reviewing a series of outbreaks in the 1960s, Aserkoff[15] estimated that 1% symptomatic infections were reported to the laboratory-based surveillance system. Using a variety of methods, including extrapolation from the carrier rate, estimating sequential error in the reporting system, and reviewing outbreaks, Chalker and Blaser[16] estimated that between 1 and 5% of infections are reported. From surveys of healthcare seeking behavior of persons with diarrhea, physician testing practices and laboratory isolation and reporting rates in active surveillance sites during 1996–1999, Voetsch[11] estimated that each reported case of laboratory-confirmed *Salmonella* infection represented approximately 38 unreported cases.

3.3. Surveys and Investigations

Because of the inherent limitations of nationwide surveillance, other studies have been performed and active surveillance has been established in selected sites to obtain a more detailed picture of the epidemiology of salmonellosis. In 1979–1980, the CDC performed a survey of all persons from whom *Salmonella* was isolated in a randomly selected, stratified sample of counties.[17] A detailed epidemiological questionnaire concerning exposures, symptoms, and complications, was administered to patients and the isolates were

examined for antimicrobial resistance. A similar survey was repeated in the same sentinel counties at 5-year intervals since 1984–1985,[18] 1989–1990,[19] and 1994–1995. Following this model, in 1996, the Foodborne Disease Active Surveillance Network (FoodNet) was established in five states.[20] Expanded to 10 states in 2005, FoodNet conducts active surveillance for *Salmonella* infections and other foodborne diseases. In addition, a proportion of *Salmonella* isolates causing these infections are examined for antimicrobial resistance through the National Antimicrobial Resistance Monitoring System for Enteric Bacteria (NARMS).[21]

The most detailed information on the epidemiology of salmonellosis has come from outbreak investigations. These investigations provide the opportunity to determine vehicles of transmission, the spectrum of illness, and risk factors for infection and for poor clinical outcomes. Case–control methods and molecular biological techniques for precisely defining the strains involved have made the outbreak investigation an occasion for extraordinarily fruitful research,[22] and outbreak investigations have in turn spawned systematic studies. Examples include studies of the decline of turtle-associated serotypes[23] and studies of the dissemination of chloramphenicol-resistant *Salmonella* Newport following an outbreak in California.[24]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification. Members of the genus *Salmonella* are gram-negative, flagellated, nonsporulating, aerobic bacilli. *Salmonella* can usually be directly isolated from primary plates inoculated with stool or rectal swabs from persons with *Salmonella* enterocolitis. The diagnostic yield may be slightly higher if one uses an aliquot of 5–10 g of feces rather than a rectal swab, particularly when attempting to identify *Salmonella* carriers, who may be shedding only small numbers of organisms. As carriers may shed *Salmonella* intermittently, culturing specimens on two or more occasions may increase the likelihood of detection. In clinical laboratories, an enrichment broth is also recommended to increase the isolation of *Salmonella* from stool specimens.[25] Three selective enrichment media are in widespread use to isolate *Salmonella*: tetrathionate broth, tetrathionate broth with brilliant green, and selenite F broth. Many microbiologists prefer to use either selenite or tetrathionate without the brilliant green dye because neither inhibits *S.* Typhi, in contrast to tetrathionate brilliant green broth. Numerous selective plating media, varying from low to high selectivity, have been used to isolate *Salmonella* from fecal specimens. The purpose of these selective media is to suppress the growth of other Enterobacteriaceae. MacConkey, eosin–methylene blue (EMB), and deoxycholate agar are media of low selectivity. *Salmonella–Shigella* (SS), Hektoen enteric (HE), and xylose–lysine–desoxycholate–citrate (XLD) agars are widely used to screen for *Salmonella* and *Shigella* because they support the growth of both organisms and are considered moderately selective media. When laboratory resources permit the use of an additional plate, highly selective media such as brilliant green or bismuth sulfite agar may be superior to the less selective media. Bismuth sulfite agar is the preferred medium for isolating *S.* Typhi. For specimens obtained from a normally sterile source such as blood or cerebrospinal fluid (CSF), using selective media has no advantage.

Following accepted microbiologic methods, colonies that are suspicious for *Salmonella* should be further identified by a chemical test. At least two representatives of each type of suspicious colony should be selected and transferred to either triple sugar iron (TSI) or Kliger's iron (KI agar). Lysine iron agar (LIA) indicates the decarboxylation or deamination of lysine and the production of hydrogen sulfide, and is particularly helpful when used in conjunction with TSI agar for the presumptive identification of *Salmonella*. The usual reaction of *Salmonella* on TSI or KI will be an alkaline slant and acid butt, and they will produce gas and H_2S. Lactose-positive strains may occasionally occur that will produce an acid slant and do not produce H_2S or gas. On LIA, the usual reaction is an alkaline slant and alkaline butt with production of H_2S. Isolates can be screened for *Salmonella* antigens using a polyvalent O or H antiserum. Colonies with typical TSI and LIA reactions that react to polyvalent O and H antisera are presumptively considered to be *Salmonella*.

If stool specimens must be transported, as is often necessary in epidemiological investigations, a swab coated with feces should be placed in a transport medium and held refrigerated until it can be examined. Commonly used transport media include Stewart's, Amies, Cary-Blair, and buffered glycerol saline. Of these, Cary-Blair is recommended as a general transport medium in the United States.[25]

Rapid diagnostic tests using enzyme immunoassay, latex agglutination, or other immunologic methods to detect *Salmonella* in feces and in foods are under development. When these methods are used in the clinical or public health setting, it will be critical to also isolate the organism itself, so that serotype, subtype, and antimicrobial resistance can be determined.

3.4.2. Serological Diagnostic Methods. Salmonellae possess somatic (O) and flagellar (H) antigens, as do other Enterobacteriaceae. The O antigenic determinants define the serogroup, and the H antigens further break these

down into more than 2,000 serotypes, according to the Kauffmann–White schema. This great variety is achieved in part because most *Salmonella* have a unique ability to express at least two separate sets of flagellar antigens. When they encounter antibodies to their usual flagella, they produce a second set, with unrelated antigens. Variations in each set of antigens and in the order in which they appear define the large number of serotypes present in each serogroup. Each serogroup has a major determinant and one or more minor somatic antigens. Serogroups A–I have been identified; most serotypes that cause human disease fall into serogroups A–E. Many clinical laboratories can readily identify serogroup using commercial polyvalent grouping antisera. Further identification of specific serotype is usually performed by a public health laboratory or other reference laboratory. Serotype determination is extremely useful in epidemiological investigations since many serotypes have specific reservoirs, host ranges, virulence, and age specificity. DNA-sequence-based approaches to defining serotypes of *Salmonella* are under active development and may soon begin replacing the traditional approach based on rabbit antisera.[26]

Since the 10 most common serotypes account for 66% of human isolates in the United States, laboratory techniques for further subtyping strains within a common serotype are often useful for epidemiological purposes.[22] Antimicrobial resistance patterns are the simplest method of further characterizing an epidemic strain. Plasmid profiles have proved useful in defining outbreak strains.[27–30] Phagetyping schemes for *S.* Typhimurium and other serotypes have been used extensively for epidemiological purposes in England and Canada and are the most practical means available for subtyping *S.* Enteritidis.[31] Pulsed-field gel electrophoresis (PFGE) of chromosomal digests shared through the PulseNet public health laboratory network has proven to be an extrordinarily useful tool in outbreak investigations and for answering specific epidemiologic questions, and now is the most common subtyping method used in the United States.[32]

The antibody response to human *Salmonella* infection has not been useful for serodiagnosis. *Salmonella* enterocolitis does not always provoke a measurable serological response, and the antibodies often cross-react with other bacteria. The Widal reaction, used historically to diagnose *S.* Typhi infection, measures agglutinating antibodies to O and H antigens of *S.* Typhi. The usefulness of this test has been severely hampered by nonspecific cross-reactivity with other *Salmonella* antigens, elevated titers due to nonspecific inflammatory disease, antibodies due to typhoid vaccination, and the suppression of O and H agglutinins by early treatment.[33] Testing for antibodies to the Vi antigen is useful for identifying typhoid carriers in epidemiological investigations (see Chapter 20).

4. Biological Characteristics of the Organism

Salmonellae are a hardy and resourceful group of organisms. They successfully parasitize a broad variety of hosts including insects, reptiles, amphibians, birds, and mammals. Although not true spore formers, they are resistant to drying and freezing and may survive for long periods in a nutrient-poor environment. The organism can survive for over 200 days in contaminated soil, 10 months in dust, more than 5 months in roach and rodent feces, and more than 4 years in dried whole egg. They multiply in food at temperatures ranging from 44 to 114°F (7–46°C) and can survive at a pH as low as 4.5.[34] Several *Salmonella* serotypes have been shown to survive quite well on the surface of fruits and vegetables[35], exploiting a possible conduit to the next colonized host.

Many salmonellae have life cycles in nature that guarantee long-term survival. Some have the ability to colonize specific loci in the gastrointestinal tract, tolerating the mild acidity of the animal's rumen or crop, or the bile in the gallbladder. Others have the ability to colonize the reproductive tracts of reptiles and birds, which means that the bacteria can infect the contents of eggs as they are formed, passing vertically to the next generation before it emerges from the shell; the evolution of this capacity well insulates such salmonellae from the environment.

4.1. Antimicrobial Resistance

The resistance of *Salmonella* to antimicrobial agents has been a matter of increasing concern. Antimicrobial resistance is important for clinical and public health reasons. Although antimicrobial treatment is not necessary in uncomplicated *Salmonella* enterocolitis and appears to prolong carriage,[36] antimicrobial treatment is essential in extraintestinal infections. The emergence of multiply resistant strains can lead to treatment failures in this setting and may require the use of new and more expensive antibiotics. Patients with antimicrobial-resistant *Salmonella* infections in FoodNet sites were more likely to have bacteremia and were hospitalized at a greater frequency and duration compared to patients with susceptible infections.[37] Antimicrobial resistance in *Salmonella* also has several important public health ramifications because simultaneous exposure to antimicrobials is associated with an increased risk of infection with resistant *Salmonella*. In one outbreak, 12 of 18 persons infected with the outbreak strain of multiply resistant *S.* Newport had taken a penicillin derivative in the week before the onset of their illness, compared to 0 of 11 persons infected with sensitive strains of *S.* Newport.[27] In most cases, illness began

within 3 days after taking the antibiotic, suggesting that the antibiotic provided a selective advantage for the resistant organism and converted asymptomatic colonization to overt infection. Exposure to antimicrobials can also lower the infectious dose for a resistant strain. This was demonstrated in a massive outbreak of multiply resistant *S.* Typhimurium infections in 1985.[38] In that outbreak, two brands of milk were contaminated, and the amount of implicated milk that persons reported drinking was an index of the dose of *Salmonella* they had received. Some persons affected by the outbreak had taken an antimicrobial to which the outbreak strain of *S.* Typhimurium was resistant just before becoming ill with salmonellosis. These persons reported drinking smaller volumes of implicated milk than ill persons not taking such antimicrobials, suggesting that a smaller dose of *Salmonella* caused illness in the former group.

At any given moment, some fraction of the population is taking antimicrobials for a variety of reasons. Because those persons appear to have heightened susceptibility to resistant strains of *Salmonella*, an outbreak due to a resistant strain may produce a somewhat larger number of cases than would an outbreak due to a sensitive strain. From 16 to 64% of cases in outbreaks of resistant *Salmonella* infections can be called "excess cases," occurring as a result of this interaction between resistance and prior or concurrent use of antimicrobials.[39] A more recent estimate of this included data from sporadic cases and suggested that 13–26% of salmonellosis cases could be attributed to the selective effect of taking an antimicrobial for other reasons.[40]

The overall level of antimicrobial resistance of *Salmonella* isolates nearly doubled from 1980 to 1990, though it has decreased somewhat since then. In the sentinel county survey of *Salmonella* isolates conducted by the CDC in 1989–1990, 31% of isolates were resistant to at least one antimicrobial,[19] a significant increase over the 16% resistance demonstrated in a similar survey in 1979–1980 (Table 1). The proportion of strains resistant to two or more agents rose from 12 to 25%. In 2004, 20% of isolates submitted to NARMS were resistant to at least one agent, 15% were resistant to two or more agents, while two strains resistant to five or more agents accounted for nearly 10% of all *Salmonella* isolates.[21] An *S.* Typhimurium strain commonly associated with definitive phage type 104 and resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline was 23% of all *S.* Typhimurium. Nearly 15% of all *S.* Newport isolates demonstrated resistance to nine antimicrobial agents, including extended spectrum cephalosporins.

Considerable evidence has accumulated about the major role of antimicrobial use in food animals that become a source of human infections with antimicrobial-resistant *Salmonella* in the United States.[41] In the 1984 sentinel county survey, the drugs to which *Salmonella* were likely to be resistant were frequently the ones that are seldom used in treating human infections, including streptomycin, nitrofurantoin, and kanamycin, yet these drugs are frequently used in agriculture and animal husbandry.[39] An increase in tetracycline resistance occurred despite the fact that the number of prescriptions dispensed for human use of

Table 1. Rates of Resistance to Specific Antimicrobials for Salmonellosis, Sentinel Country Surveys, 1979–1980, 1989–1990 and NARMS, 2004[a]

	Percent of isolates resistant

tetracycline decreased 61% between 1973 and 1984. During that period, tetracyclines continued to be used extensively as growth enhancers, particularly among cattle. More compelling evidence comes from outbreak investigations in which resistant strains have been traced from ill persons back through the food distribution chain to the farm. In one outbreak a multiply resistant strain of *S.* Newport was traced from ill persons in one state back through supermarket distribution and the meat processing plant to a farm where the beef cattle had been fed nontherapeutic doses of chlortetracycline.[27] In another outbreak, almost 1,000 persons in California became infected with a strain of chloramphenicol-resistant *S.* Newport with a unique plasmid profile. The chain of transmission was followed from ill persons, to hamburger, to beef from meat packers, to slaughterhouses, and, finally, to cows and calves on farms where chloramphenicol had been used.[29] At each stage, the unique epidemic strain of *S.* Newport was isolated. More recently, the emergence of a highly resistant strain of *S.* Newport infections in the Northeastern United States was heralded by outbreaks on dairy farms.[42] Experience in other countries suggest that decreased use of antimicrobials in animal feed may result in a decrease in antimicrobial-resistant strains of *Salmonella* causing human infection.[43]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Between the inception of national laboratory-based *Salmonella* surveillance in 1962 and 1976, the incidence of reported *Salmonella* isolations in humans increased slightly. Between 1976 and 1986, the incidence rose by more than 60%, from 10.6/100,000 in 1976 to 17.4/100,000 in 1986, declined to 15/100,000 in 1994, and was 11 per 100,000 in 2005. This overall trend includes a sharp peak in *S.* Typhimurium infections related to a massive milk-associated outbreak in 1985 with more than 16,000 culture-confirmed cases, a dramatic increase in the isolation rate of *S.* Enteritidis in the 1980s and 1990s, and an increase and subsequent decrease in *S.* Heidelberg (Figure 2). This increase in reported isolates was paralleled by an increase in clinical cases reported to the *Morbidity and Mortality Weekly Report* during the same period (Figure 1). The actual number of infections occurring annually is likely to be more than 1.4 million, the vast majority of which are mild and undiagnosed (see Section 3.2). In FoodNet, the incidence of *Salmonella* infections has not changed significantly from the baseline period of 1996–1998 to 2006.[44] The top six serotypes in FoodNet sites showed disparate trends during this period, with the estimated incidence of

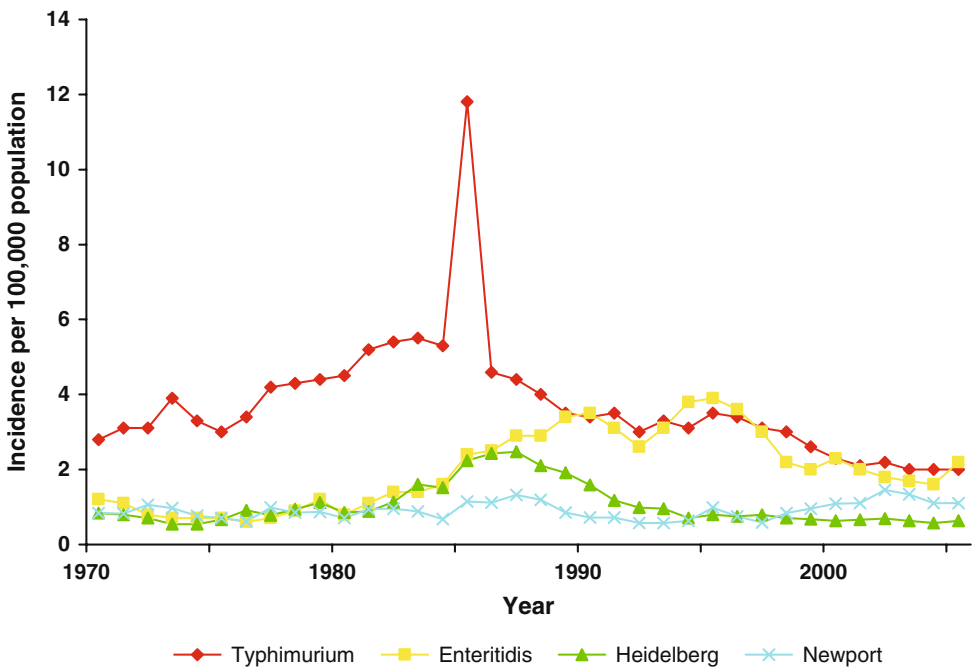

Figure 2. Isolation rates for selected serotypes of *Salmonella* in the United States from 1970 to 2005. From the CDC[51] (1985 peak for *S.* Typhimurium includes reported isolates from massive outbreak with >16,000 culture-confirmed infections.[38]).

Salmonella Javiana, *S*. Newport, and *S.* Enteritidis increasing, *S*. Heidelberg and *Salmonella* Montivideo not changing, and only *S. Typhimurium* decreasing.

The epidemiology of *Salmonella* infection varies considerably by serotype. *Salmonella* Typhimurium accounts for 15–25% of human isolates and comes from a variety of different sources, including meat, poultry, and eggs. *Salmonella* 4,5, 12:i:-, a monophasic serotype related to*S.* Typhimurium, has emerged as an important cause of human salmonellosis, first in Europe as a multidrug-resistant strain associated with pork[45] and more recently as a susceptible strain in the United States, with a possible poultry reservoir.[46] *Salmonella* Enteritidis remains a dominant serotype in the United States and many other industrialized nations.[47,48] This serotype is strongly egg associated: between 1985 and 1991, 82% of *S.* Enteritidis outbreaks with known vehicle were egg associated and the same was true for sporadic infections, though now consumption of poultry is also an important source of this serotype.[49–51] The 10 most common serotypes account for 66% of infections. Five of these are also among the top 10 reported from nonhuman sources (Table 2).[52] *Salmonella* Newport has an important bovine reservoir. *Salmonella* Heidelberg and *S*. Montevideo appear to have poultry reservoirs. *Salmonella* Javiana is increasing in frequency, has caused outbreaks related to produce, and may have a reservoir in amphibians.[53, 54]

The general increase in the incidence of salmonellosis in the United States after 1950 parallels similar increases seen in many industrialized countries. Several factors contributed to the increase, including changes in methods of raising food animals intensively and shipping them to slaughter and the increased mechanization of animal slaughter. Changes in the cooking practices of the population are also of concern, including a greater reliance on precooked convenience foods, on foods eaten outside of the home, and a decline in what children learn about cooking at home and in school. The more recent decrease in salmonellosis may reflect greater attention to contamination control in animal husbandry and slaughter, as well as efforts to improve food-handling practices.

The prevalence of *Salmonella* carriage among the general population is not known with accuracy in the United States, but has been estimated to be between 0.15 and 0.2%.[16,55]

5.2. Epidemic Behavior and Contagiousness

Most cases of human salmonellosis result from contaminated food, although infection has been transmitted by an enormous variety of other vehicles (see Section 6). Cases may occur as part of recognized outbreaks but the majority occur as sporadic cases.

Outbreaks of salmonellosis that are reported to the CDC account for less than 10% of reported isolates in most years. In 1998–2002, the mean size of reported outbreaks of *Salmonella* infections was 28 persons, suggesting that only relatively large outbreaks were identified and reported.[12] In the 1979–1980 sentinel county survey, only 21% of reported isolates were associated with outbreaks or linked to other cases reported to local health departments. The remaining cases were not associated with other cases or recognized outbreaks and are considered "sporadic."[17] Case–control studies of sporadic cases may relate illness to the same exposures as outbreaks, and in some cases it has been possible to link many "sporadic" cases to a common source.[28,50]

Salmonella outbreaks often have distinctive patterns. Most distinctive is the explosive outbreak from a common source of exposure, dramatically exemplified by the

Table 2. The Ten Most Common Serotypes Identified Among Human *Salmonella* Infections and Nonhuman Sources in 2005[a]

Human			Nonhuman		
Serotype	No. of isolate	%	Serotype	No. of isolate	%

[a]From the CDC.[51]

massive milkborne outbreak in Illinois in 1985 involving more than 16,000 reported cases.[38] A pattern more difficult to recognize is the prolonged epidemic curve associated with continued exposure to a widely distributed contaminated food source or product, such as the outbreaks due to *S.* Newport-contaminated roast beef in several northeastern states,[28] *Salmonella* Eastborne in contaminated chocolate,[56] *Salmonella* Newbrunswick in powdered milk,[57] marijuana contaminated with *Salmonella* Muenchen,[30] or *Salmonella* Tennessee in peanut butter.[58] These outbreaks are most easily recognized when they involve an unusual serotype. Molecular subtyping of *Salmonella* isolates by PFGE in state public health laboratories and comparison of similar patterns through the PulseNet laboratory network have allowed for detection of widespread outbreaks among more common serotypes, such as *S.* Typhimurium due to contaminated ground beef[59] and *S.* Newport associated with tomatoes.[60] It is likely, though, that many small foodborne outbreaks occur in families, and this has led to difficulty determining the relative importance of foodborne versus intrafamilial spread. In one study, 39% of cases of salmonellosis in infants were preceded by gastroenteritis in an adult family member, suggesting that intrafamilial spread to infants may follow salmonellosis in other family members.[61] In general, sustained person-to-person transmission of salmonellosis is unlikely (see Section 5.8).

5.3. Geographic Distribution

Nontyphoidal salmonellosis appears to be predominantly a disease of industrialized nations and industrialized agriculture. Worldwide, the proportion of *Salmonella* infections due to nontyphoid serotypes of *Salmonella* appears to increase with the degree of economic development, while the proportion due to *S.* Typhi declines (Figure 3).

Isolation rates vary considerably across the United States. Differences in reported isolation rates between states must be interpreted with caution since it has been shown that isolation rates correlate with per capita state laboratory expenditure and with the number of stool cultures submitted to the state laboratory.[62] Consistent regional differences exist, however, with the highest rates observed in New England, Middle Atlantic, and Pacific states and the lowest rates in the West and West–North Central states, suggesting that real variations may exist in *Salmonella* exposure.

Within the United States, considerable geographic variation exists among serotypes and over time. For example, *S.* Enteritidis has been particularly common in the northeastern part of the United States. Though it has recently declined, it often greatly exceeded the number of *S.* Typhimurium isolates there in that region. *Salmonella* Enteritidis increased rapidly in the West in the 1990s, where *S.* Newport and *Salmonella* Dublin have long been concentrated (Figure 4). *Salmonella* Javiana is associated

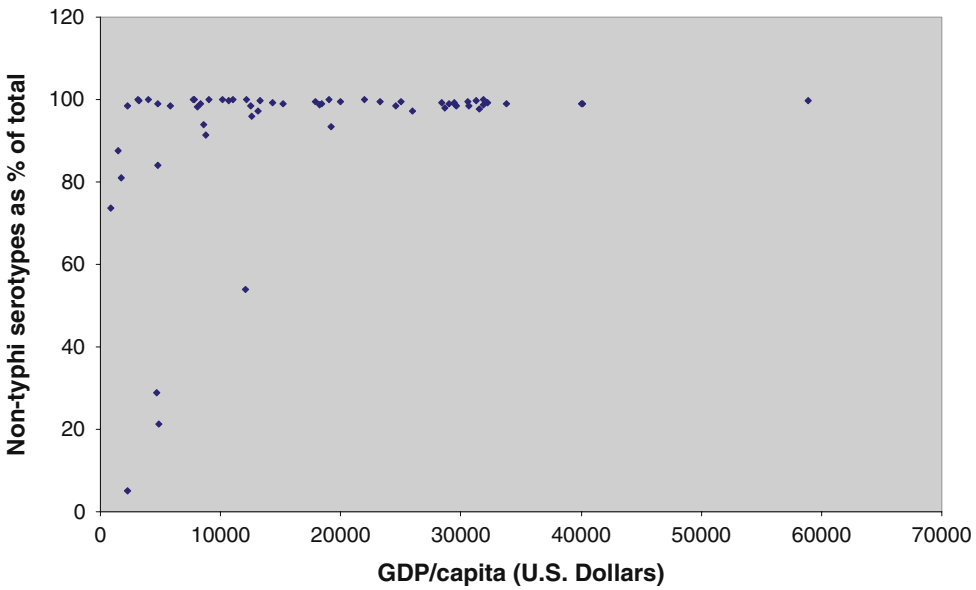

Figure 3. Nontyphoid serotypes as a percentage of all *Salmonella* isolates (including *S.* Typhi) as a function of per capita gross national product, showing the increasing importance of nontyphoidal salmonellosis with increased economic development. Data from Global *Salmonella* Surveillance country databank accessed via the World Wide Web at http://www.who.int/salmsurv/activities/databank/en/ and the United States Central Intelligence Agency CIA World Fact Book accessed via the World Wide Web at https://www.cia.gov/library/publications/the-world-factbook/.

with the Southeast, S. Oranienberg with the Southwest, and S. *Weltevreden* with Hawaii.[3]

5.4. Temporal Distribution

Salmonella isolation shows a consistent seasonal pattern, with a summer and fall peak. This seasonal pattern is likely the result of seasonal variation in levels of infection of animals and in the resulting contamination of foods, as well as from the more rapid growth of *Salmonella* at warmer temperatures. The amplitude of the seasonal variation varies among the different serotypes.

5.5. Age and Sex

The age- and sex-specific isolation rates for *Salmonella* is shown in Figure 5. The isolation rate is highest in the first year of life, peaking at more than 160 cases per 100,000 population per year in the second month of life.[63] The rate of infection declines rapidly among individuals 10–19 years old and then begins to rise among those older than 60. Some degree of detection bias probably exists, since infants and the elderly may be more likely to have stool cultures performed when they are diagnosed with gastrointestinal infection. Nonetheless, this pattern probably reflects real age-specific differences in host susceptibility and in exposure rates. Substantial differences exist in the age specificity among the various serotypes, which are poorly understood but which presumably reflect differences in vehicle of transmission or of underlying serotype-specific immunity.

5.6. Race

Data on race are not routinely collected in national laboratory-based surveillance and no national data on the

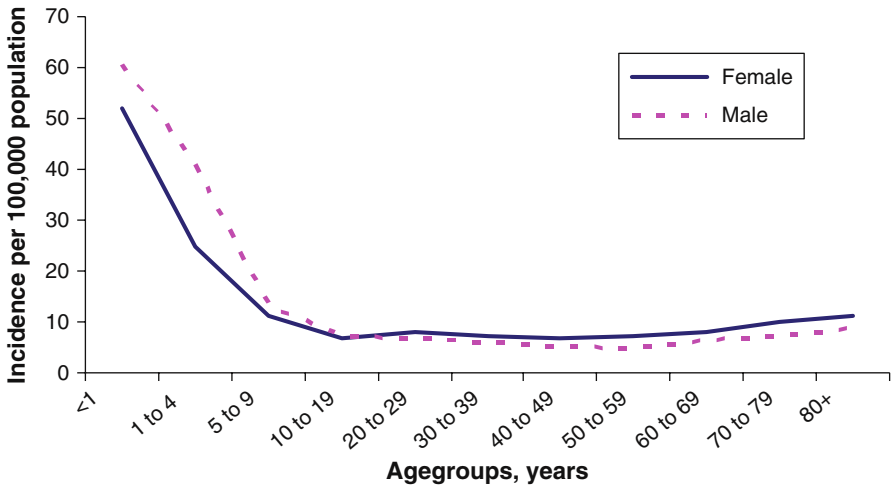

Figure 5. *Salmonella* isolation rates by age and sex, per 100,000 population, United States, 2005. From the CDC.[51]

relative isolation rates by race have been reported. For unknown reasons, the risk that a *Salmonella* infection will be caused by a resistant strain is higher among black than white infants.[19]

5.7. Occupation

Few data are available to demonstrate that high-risk occupations for salmonellosis exist. Some studies have found higher rates of *Salmonella* carriage among food handlers, which may reflect their high level of contact with raw food and the frequency with which they are cultured.[64] In the past, sewage workers were considered to be at high risk of *Salmonella* infections, particularly typhoid fever, but existing evidence does not suggest that they are currently at increased risk.[65]

5.8. Occurrence in Different Settings

Salmonella outbreaks may create particular problems at institutions, including schools, prisons, nursing homes, hospitals, mental hospitals, and institutions for the developmentally disabled. Between 1963 and 1972, 28% of all *Salmonella* outbreaks reported to the CDC occurred in institutions; two thirds of these occurred in acute-care hospitals, pediatric wards, and newborn nurseries.[66] Institutional outbreaks tend to be more serious than those in other settings; the case-fatality rate for all institutional outbreaks between 1963 and 1972 was 2.3% and for those occurring in nursing homes, 8.7%. In the past, nosocomial outbreaks have occurred due to the use of contaminated medical and pharmaceutical products including carmine dye, pancreatic enzymes, platelets, and extracts of thyroid, adrenal cortex, pancreas, and pituitary.[66] Other important hospital outbreaks have been caused by contaminated foods, including powdered eggs, dried milk, and human breast milk.[67] The number of nosocomial *Salmonella* outbreaks reported to the CDC has decreased in recent years, but outbreaks due to *S.* Enteritidis in shell eggs have occurred in nursing homes and hospitals, reflecting the importance of eggs as the vehicle of *S.* Enteritidis.[46] Among 52 foodborne outbreaks of known etiology in nursing homes reported to the CDC between 1975 and 1987, 27 (52%) were caused by *Salmonella*, particularly *S.* Enteritidis.[68] *Salmonella* accounted for 81% of deaths associated with these outbreaks.

Although person-to-person spread is frequently suspected in institutional outbreaks of *Salmonella*, it has been rigorously demonstrated in relatively few. Most recent institutional outbreaks are caused by food products of animal origin or contaminated produce. The risk of secondary transmission within hospitals probably varies according to the patient population and setting. Transmission is particularly likely to occur in neonatal nurseries, where peripartum transmission may result in an infected infant and the high level of nursing intervention and the susceptibility of neonates to *Salmonella* predispose to secondary transmission. On regular hospital wards the risk may be considerably less. No secondary transmission was documented in a hospital outbreak involving more than 200 nurses who developed salmonellosis after a "nurse appreciation day" meal.[69] Infection control measures included emphasis on hand washing and exclusion of nurses with enterocolitis until symptoms resolved; negative stool cultures before returning to duty were only required for those working in the neonatal

or adult intensive care unit, nursery, or renal dialysis unit. However, transmission to a patient did follow an outbreak of illness among family practice residents, emphasizing the need for vigilance and rigor in basic prevention.[70]

5.9. *Salmonella* Infections in the Compromised Host

A variety of conditions have been associated with increased risk of *Salmonella* infections, including gastric surgery, decreased gastric acidity, sickle-cell anemia, lymphoma, Hodgkin's disease, metastatic cancer, and infection with human immunodeficiency virus (HIV).[55,71,72] These are related to different mechanisms of defense against *Salmonella* infections (see Section 7). Patients with sickle-cell anemia and other diseases that compromise the reticuloendothelial system have an increased rate of *Salmonella* bacteremia and *Salmonella* osteomyelitis. The decreased ability to clear opsonized bacteria of these patients and perhaps the increased availability of iron may play a major role.[73] Patients with neoplastic disease are also at increased risk of salmonellosis, and lympho-proliferative disorders appear to be more strongly associated with salmonellosis than are solid tumors[72] (see Section 8).

5.10. *Salmonella* Infections and AIDS

Salmonella has emerged as an important pathogen among patients with acquired immunodeficiency syndrome (AIDS). In a San Francisco study, the annual incidence of salmonellosis among patients with AIDS was almost 20 times higher than that in men in a similar age group who did not have AIDS.[71] The proportion of bacteremic *Salmonella* infections is also increased in patients with AIDS; *S.* Typhimurium and *S*. Dublin were more likely to cause bacteremia among these patients than among patients without HIV infection. *Salmonella* bacteremia in patients with AIDS often occurs in the absence of an identifiable episode of enterocolitis and frequently recurs after appropriate antimicrobial treatment.[74] Recurrent *Salmonella* bacteremia was made an indicator disease in the AIDS case definition in 1987. *Salmonella* bacteremia in HIV-infected individuals may precede and foreshadow the development of AIDS; in one-third of the patients in the San Francisco study, salmonellosis occurred shortly before they were diagnosed to have AIDS.[71] Increases in *Salmonella* bacteremia, particularly caused by *S.* Enteritidis and *S.* Typhimurium, mirror the demography of the AIDS epidemic.[75,76] *Salmonella* infections represent a large and potentially preventable source of mortality in this group. Patient education and the avoidance of high-risk foods have an important role in prevention.

6. Mechanisms and Routes of Transmission

Human infections are often related directly or indirectly to infection in animals. Transmission can occur via a variety of specific routes, including foodborne, waterborne, animal-to-person contact, person-to-person contact (either direct or indirect), and transfusion. However, up to 95% of infections with *Salmonella* in the United States are foodborne in origin.[77] Data on the sources of foodborne salmonellosis outbreaks indicate that foods of animal origin, especially poultry products, are the most common sources (Table 3). Produce items caused more than 10% of recent salmonellosis outbreaks, consistent with a trend toward more outbreaks of all etiologies due to fresh produce.[78] The typical foodborne outbreak is the result of at least two food-handling errors: one that permits the contamination to occur or persist and another that permits sufficient bacterial growth to reach the infectious dose.

The epidemiological complexity of tracing the sources of specific contaminated foods can be challenging. A few serotypes are associated with a specific vehicle. For instance, *S*. Dublin infection is strongly associated with the consumption of raw milk and *S.* Enteritidis with undercooked eggs.[47,79] Infection with a multidrug-resistant strain of *S*. Newport has been linked to beef in both outbreak and sporadic case–control studies.[80 81] When a convenient bacteriologic strain marker is available, it has been possible to retrace the chain of transmission to farms of origin.[27,29] If the serotype is rare, or the molecular subtype by PFGE is available, it may be possible to trace it even further back. For instance, the international epidemic of *Salmonella* Agona infections was traced to Peruvian fish meal, used in poultry

Table 3. Foodborne Outbreaks of Salmonellosis Reported 1998–2002, by Impilcated Vehicle[a]

Food vehicle	No. of outbreaks	Percent of outbreaks of known vehicle
Eggs	57	15
Poultry	50	13
Vegetable	25	7
Fruits and nuts	18	5
Pork	17	5
Dairy	11	3
Beef	9	2
Finfish/Shellfish	6	2
Other foods	6	2
Multiple foods	177	47
Known	376	
Unknown	209	
Total	585	

[a] Adapted from Lynch.[12]

feed, that introduced this formerly rare serotype to several continents simultaneously, where it has since persisted in poultry.[82] In the United States, several serotypes have been associated increasingly, though not exclusively, with particular fruit and vegetable food vehicles, including widespread outbreaks of *S.* Javiana and *S*. Newport infections due to domestic tomatoes and recurrent outbreaks of *Salmonella* Poona infections from imported cantaloupes.[83,84] Recurrent outbreaks due to one PFGE-defined strain of *S*. Newport associated with tomatoes have been traced to farms in one state by isolation of the outbreak strain in the growing environment.[60] *Salmonella* can be introduced and perpetuated on a farm through contaminated feeds, the introduction of infected stock, or by wild animals.

Foods may be contaminated in different ways: meat by contents of the gastrointestinal tract during the slaughter process or in vivo if the animal was bacteremic at the time of slaughter; milk by feces during the milking process or by mastitis in the milked cow; prepared foods during processing by the use of contaminated ingredients or by cross-contamination within the processing plant itself. In the kitchen, food may be cross-contaminated from raw foods or other sources. Once introduced, *Salmonella* can survive and multiply in many different foods, including meats, dairy products, and produce. Although food handlers are often found to be infected in the course of investigating a foodborne outbreak investigation, they are most often infected because of their exposure to contaminated foods and are less commonly shown to be the source of the contamination themselves.[55] Food may be a source of *Salmonella* even when not consumed. In a recent FoodNet case–control study of salmonellosis in infants, the identified risk factors included having ridden in grocery cart next to meat or poultry.[85]

In addition to foodborne transmission, large waterborne outbreaks of salmonellosis have occurred, when drinking water supplies have been contaminated in the absence of proper chlorination.[86,87]

Salmonella can reach an individual from animal reservoirs via a variety of other routes. Persons in direct contact with ill animals may become infected themselves. Pet turtles, which were almost universally colonized with *Salmonella*, emerged as an important source of the disease in the United States in the early 1970s.[88] Pet iguanas and other reptiles are now an important source of salmonellosis.[88] Chameleons, aquarium fish, chicks, and other potential pets may also be colonized with *Salmonella* and may occasionally be sources of infection.[90,91] Marijuana contaminated with *S.* Muenchen was the source of an interstate outbreak probably due to the presence of animal feces.[30] A series of outbreaks of *Salmonella* Cubana infections was traced to carmine dye made from powdered insects that was used as a marker of gastrointestinal motility.[92] An outbreak of *Salmonella* Arizona infections was traced to powdered rattlesnake capsules sold as a folk remedy.[93] Multidrug-resistant *S.* Typhimurium was transmitted by contact with hamsters sold as "pocket pets."[94]

Salmonellosis can also be transmitted from one infected person to another, particularly among a group of unusually susceptible individuals (see Section 5.2). Foodborne outbreaks can be linked to infected food handlers, who may sometimes be the source; often the food handler was actually infected by the food.[95] Nosocomial outbreaks of salmonellosis that are not foodborne typically occur in the nursery, and transmission from one child to the next occurs on the unwashed hands of the healthcare worker or via medical equipment. Many other routes of nosocomial transmission are possible. Infection can follow transfer of the organism via endoscope from one patient to the next.[23] *Salmonella* Kottbus has been transmitted through unpasteurized human milk, collected for infants at a human milk bank, from a woman with asymptomatic mammary carriage.[96] *Salmonella* Choleraesuis was transmitted through platelet transfusions after the platelets were collected from a bacteremic donor.[97] Infection has been transmitted from soiled patient bedclothes to hospital laundry workers.[98]

Although epidemiological data from developing countries are limited, transmission of salmonellosis in those countries may include all of the above routes. Nosocomial reservoirs may be of greater importance than in industrialized countries, particularly for multiply resistant and invasive strains, such as those described in Brazil, Rwanda, and the Ivory Coast.[99–101]

7. Pathogenesis and Immunity

The incubation period after ingestion of *Salmonella* usually ranges from 12 to 48 h, though longer incubation periods have been documented[102]. The pathogenesis of *Salmonella* infections is incompletely understood. The multiplicity of serotypes and animal hosts involved introduces much complexity; a serotype that is nonpathogenic in one animal species may produce severe illness in another. Laboratory models need to be interpreted with caution. For instance, *S.* Typhimurium infections in the mouse may be more analogous to *S.* Typhi than to *S.* Typhimurium infections in humans. The clinical expression of infection is affected by serotype and strain of the bacteria; the status of the underlying health and gut flora of the host; and the dose, vehicle, and route of transmission.

Following ingestion, the organisms traverse the gastric acid barrier and multiply in the small intestine. The bacteria penetrate and damage the intestinal mucosa, are ingested by macrophages, and may multiply in a limited fashion in mesenteric lymphoid tissues. In severe invasive infection, bacteremia and focal infections in distant tissues occur.

After more than a century of study, the virulence properties of these organisms remain incompletely understood. Many potential factors and mechanisms have been described, which may be variably present in different serotypes and strains. Some have been well characterized and undoubtedly more remain to be discovered. The O-specific side chain portion of lipopolysaccharide (LPS) is associated with invasiveness, and rough mutants with incomplete O-side chains have markedly diminished virulence.[103] The lipid A portion of LPS is responsible for the endotoxin-mediated effects of the *Salmonella* infection.[104]

The process includes several distinct steps, no single one of which explains the entire pathogenic spectrum: (1) Attachment and penetration. Adhesins facilitate the attachment of salmonellae to intestinal mucosal cells and may be necessary for mucosal invasion.[105] *Salmonella* can induce ordinarily nonphagocytic mucosal cells to engulf them, an unusual ability that gives them rapid access to protected intracellular sites.[106] (2) Inflammation and tissue destruction. The fever, diarrhea, and evidence of colitis that often accompany salmonellosis may be the result of local inflammation, effects of bacterial endotoxin, or of specific cytotoxins that cause mucosal cell death.[107] (3) Intracellular multiplication in macrophages. Lethality in the mouse model is associated with the ability to multiply in macrophages, which may be a function of the presence of flagella, plasmid-associated factors, and an ability to slow acidification within the macrophage.[108–110]

The outcome of infections is partly dependent on the number of ingested bacteria that reach the intestine. Small numbers of ingested *Salmonella* may cause transient asymptomatic intestinal colonization, while larger doses of the same strain may produce overwhelming or even fatal illness. The minimum dose necessary to cause illness varies with the serotype, the vehicle, and a variety of host factors. Although early volunteer studies indicated the infectious dose ranged from 10^5 to 10^{10} organisms, the minimal dose that causes illness in some circumstances may be substantially lower, even as low as 10 organisms.[111]

There are several major barriers in the host's defense against *Salmonella* infection. The first is gastric acidity, which can reduce the number of viable organisms by several logs within minutes. The degree of protection provided by gastric acid depends on the vehicle of infection; *Salmonella* may traverse the stomach more rapidly when consumed in liquids than in solid foods, and contaminated foods that buffer gastric acid well, such as chocolate, cheese, or milk, may transmit infection more efficiently than foods that do not. Persons with more neutral gastric pH, such as the elderly, those taking antacids or other antiulcer medications, and those who have had gastric surgery, are at increased risk for infection.[17,55]

The normal intestinal flora are a second major barrier to infection with salmonellosis. Disruption of the flora, particularly with antimicrobials that are active against the anaerobic flora such as penicillin or tetracycline, decreases the infectious dose needed to produce illness.[38,112] If the infecting strain is resistant to the antimicrobial used, therapy for an unrelated condition may convert a silent transient colonization to overt clinical infection, when the normal flora are suppressed.[27,113] Cellular immunity is the third major defense against bacteremia and invasive illness. This can be overcome in the normal host by certain highly invasive serotypes, such as *S.* Choleraesuis, or *S.* Paratyphi, or by very large doses of other serotypes.[114] Hemolytic conditions, such as sickle-cell disease, bartonellosis, or malaria, predispose to invasive infection.[115] Persons with defective cellular immunity, such as those receiving immunosuppressive therapy, with advanced malignancies, or infected with HIV, are also at increased risk for invasive illness (see Sections 5.9 and 5.10).

Immunity to *Salmonella* infection is partial at best. In volunteer experiments, patients rechallenged with the homologous strain became ill a second time, although with somewhat milder symptoms than on initial exposure.[116] In animal models, experimental vaccines can prevent death, but not infection. A vaccine against *S.* Choleraesuis, an economically important pathogen in swine, has now been licensed for use in swine.[117]

The humoral response of humans to experimental infection has been defined. Agglutinating antibodies develop against the somatic (O) and flagellar (H) antigens, even following asymptomatic infections.[118] These antibodies do not always appear, they wane after several months, and sufficient cross-reactions occur with other enteric bacteria that they have been of little diagnostic or epidemiological utility. The nature of the cellular immune response to salmonellosis in humans has not been clearly defined.

8. Patterns of Host Response

The host response to *Salmonella* infection includes asymptomatic colonization, gastroenteritis, focal soft tissue infection, meningitis, bacteremia, sepsis, and death. The pattern of host response may be dictated by the virulence of the specific strain, the size of the inoculum, and specific host

factors including age, gastric acidity, immunologic competence, prior antimicrobial exposure, and specific illnesses. Disorders of the gastrointestinal tract (gastrectomy, achlorhydria, esophageal, gastric, or intestinal malignancies) may predispose to enterocolitis, and defects of cellular immunity (leukemia, lymphoma, HIV infection) or reticuloendothelial cell function (sickle-cell anemia, bartonellosis, malaria) may predispose to bacteremia and invasive disease.[55,72] Age is also an important determinant of host response. Bacteriuria, and frank urinary tract infection with *Salmonella,* is more frequent among older women, and is associated with specific serotypes, such as *S.* Tennessee.[119] The incidence of salmonellosis is higher among infants and the elderly and the frequency of bacteremia is higher in both of these age groups.[120] The mortality of *Salmonella* infection is also considerably higher at the extremes of age, as demonstrated by outbreaks in nurseries and nursing homes.[66]

After infection occurs, the organism persists in the gut for a median of 5 weeks, even after all symptoms have ceased. This convalescent carriage can be prolonged in young children.[121] Paradoxically, treatment with antimicrobials does not shorten the duration of carriage, but typically prolongs it, suggesting that the final resolution of infection may depend on the competitive effects of other gut bacteria as well as on the immune response of the host.[36,122] In persons of the HLA-B27 genotype, acute salmonellosis can trigger the reactive arthropathy, Reiter's syndrome, leading to prolonged and recurrent episodes of joint pain, urethritis, and uveitis.[123]

The most important determinant of host response may be the organism itself. Certain serotypes appear to be unusually virulent and are isolated more often from the blood and CSF relative to their overall isolation rate. *Salmonella* Choleraesuis, *S.* Dublin, and *S.* Paratyphi A, B, and C are more commonly isolated from blood, and *Salmonella* Panama, *Salmonella* Heidelberg, and *Salmonella* Saintpaul are disproportionately common isolates from CSF.[124,125] Some serotypes, such as *S.* Tennessee, are disproportionately common in urine specimens, particularly in older women, and may be uropathogenic.[119]

8.1. Clinical Features

The clinical manifestations of infection with nontyphoidal *Salmonella* can be grouped into several clinical syndromes with some overlap.

Acute enterocolitis, or gastroenteritis, is the most common syndrome of *Salmonella* infection. Initial symptoms often include nausea, vomiting, and headache, followed by abdominal cramps and diarrhea, which are the predominant manifestations. The stools are normally loose and of moderate volume; blood is occasionally seen. Voluminous, cholera-like diarrhea has been reported, as have small-volume, dysenteric stools associated with tenesmus, but these are unusual manifestations. Fever, often accompanied by chills, is present in about 50% of patients. Diarrhea usually lasts 3–7 days, but may be prolonged.[55] The larger the dose of organisms ingested, the shorter the incubation period and the more likely the patient is to have fever, vomiting, and a more severe illness in general.[126]

The enteric fever syndrome is classically associated with *S.* Typhi, but may at times occur with other serotypes. This syndrome is characterized by a prolonged course with prominent and sustained fever, anorexia, abdominal pain, splenomegaly, and headache. Respiratory symptoms may be prominent and hepatomegaly, neurological manifestations, and relative bradycardia may occur in nontyphoidal enteric fever. Complications include intestinal hemorrhage and perforation, myocarditis, seizures, and localized infections, but are less common than in enteric fever due to *S.* Typhi.

Bacteremia without enteric fever may also occur due to nontyphoidal *Salmonella*. In children, "silent" bacteremia during enterocolitis may occur in 5–10% of patients,[127] but *Salmonella* bacteremia with high fever may occur without other signs of enterocolitis or enteric fever, particularly among persons with AIDS. Localized extraintestinal infections may result. Endarteritis, particularly infection of atherosclerotic aortic aneurysms, may occur in patients with preexisting atherosclerotic disease. Endocarditis is rare, and usually occurs on abnormal valves; infection of prosthetic heart valves has also been reported. *Salmonella* Choleraesuis is responsible for a disproportionate number of endothelial infections. These infections can rarely be cured by antibiotics alone and surgical intervention is often necessary.[55] *Salmonella* meningitis occurs primarily in infants, and even with adequate antibiotic therapy, the mortality is high. Osteomyelitis and arthritis due to *Salmonella* may occur in normal hosts but are more common in immunocompromised persons, particularly those with hemolytic disorders. *Salmonella* is the most common cause of osteomyelitis in patients with sickle-cell anemia. Other complications of *Salmonella* bacteremia include pneumonia, empyema, endocarditis, intracranial abscess, urinary tract infections, and abscesses of the spleen, liver, and other soft tissue.[115]

8.2. Diagnosis

The diagnosis of *Salmonella* enterocolitis is made by stool culture. The diagnosis should be considered in any patient with moderate-to-severe gastroenteritis; the presence

of headache or fever makes the possibility of this disease more likely. Fecal leukocytes may be present, but are not diagnostic. The differential diagnosis of *Salmonella* enterocolitis includes viral gastroenteritis and other bacterial enteric infections, including those caused by *Shigella*, enterotoxigenic, enterohemorrhagic, and enteropathogenic *Escherichia coli, Campylobacter* species, *Vibrio* species, and *Yersinia enterocolitica*. The disorder must also be differentiated from toxin-mediated foodborne illnesses including those caused by *Staphylococcus aureus, Bacillus cereus*, and *Clostridium perfringens*. Compared to patients with these toxin-mediated disorders, persons with salmonellosis usually have less prominent vomiting and are more likely to have prolonged diarrhea and fever. The shorter incubation periods of toxin-mediated foodborne illness can be an important clue to distinguish them from salmonellosis. The presence of frequent, small-volume, bloody or mucus-streaked stools, tenesmus, and large numbers of fecal leukocytes makes campylobacterosis or shigellosis more likely than salmonellosis. A history of ingestion of raw milk, undercooked eggs or meat, or exposure to lizards or farm animals within the 48 h before onset of illness may suggest the diagnosis of salmonellosis. Ultimately, however, the diagnosis depends on cultures of stool, or in the case of high fever or invasive disease, blood, CSF, or other body fluids.

9. Control and Prevention

The control of salmonellosis depends on understanding the routes and cycles of transmission well enough to interrupt them. Control of foodborne salmonellosis can occur at many levels, at the farm, during truck transport, the slaughter plant, or food production facility, to the cook and consumer. Once the transmission is understood and the critical control points are understood, intervention can be highly successful.

Interventions at the level of the farm can succeed. In Scandinavia, the prevalence of salmonellae in chicken flocks has been greatly reduced by exposing the chicks to normal fecal flora shortly after they hatch, thus increasing their resistance to subsequent colonization with *Salmonella*.[128] In many countries, including the United States, a serotype that is highly pathogenic to poultry—*S*. Gallinarum—has been virtually eradicated by a vigorous flock- and hatchery-based program of serological testing and destruction of infected birds.[129] In Denmark, a cost-effective program of testing swine and eggs for serologic evidence of infections, and elimination of infected flocks or swine herds has greatly reduced the frequency of contamination of those food products.[130]

Animals entering the slaughter plant may be free of *Salmonella*, may have silent colonization, or may be ill or even moribund with systemic salmonellosis. Visual inspection methods will detect some of the last group; the proportion of slaughtered cattle that are moribund correlates with the level of carcass contamination.[29] However, visual inspection cannot detect silent colonization, which is far more common. Slaughter and inspection safety practices based on the Hazard Analysis – Critical Control Point (HACCP) method were introduced in the late 1990s, and include performance measures based on the frequency with which *Salmonella* is isolated from the final product.[131] Condemned carcasses are sold for pet food or are sent to rendering plants to be converted to meal used to make animal feed. Unfortunately, the rendered product is often recontaminated with *Salmonella* before it leaves the rendering plant, so that animal feed in the United States is often contaminated with *Salmonella*. Many countries, but not the United States, require the routine pasteurization of animal feeds to interrupt this cycle.[132]

Salmonellosis related to fresh fruits and vegetables can be controlled if the level of contamination occurring in the field and during processing can be reduced. Strategies include using uncontaminated sources of water for application to edible portions of the plant, providing adequate sanitary facilities for field workers, washing fruits and vegetables after harvest in carefully disinfected water, shipping them on ice made from disinfected water, and not cutting or slicing them until immediately before consumption. Guidelines for good agricultural practices have been proffered[133] but implementation of industry-wide food safety programs for specific produce commodities has been challenging. For instance, raw sprout-related outbreaks continue to be a problem; some due to incomplete adherence to recommended sprout disinfection and testing protocols.[134]

Changes in food production practices can increase or decrease the likelihood of contamination of the finished product. For example, the pasteurization of milk protects the consumer against many raw-milk-associated pathogens, including *Salmonella*. Because of documented risk of salmonellosis and campylobacteriosis, the interstate sale of raw milk was banned in 1987. Outbreaks related to contaminated fruit juices decreased following implementation of heat treatment as part of a juice HACCP program.[135] In a series of *S*. Newport outbreaks traced to precooked roast beef in the late 1970s, the cooking process was found to be inadequate to kill *Salmonella* present on raw beef. These outbreaks ended after the required time and temperature of cooking were changed in 1980 and 1981.[136] New technologies may reduce contamination of poultry during slaughter and processing, including trisodium phosphate dips that rinse

Salmonella off carcasses, air-cooling devices to replace the cold water chill tanks, better eviscerators that decrease the likelihood of rupture of the crop or gut, and better decontamination procedures for the machinery used. Irradiating raw meat and poultry would be a singularly effective step in controlling salmonellosis, but one which thus far has not been a major commercial success.[137] Outbreaks traced to toasted oat breakfast cereal, peanut butter, and other low-moisture-processed foods illustrate the hazard that foods can be contaminated in the food factory environment, leading to widespread outbreaks.[138,57] Vigilance by the industry itself, and rigorous application of the HACCP approach to make sure that such foods are properly processed and do not become recontaminated could prevent such outbreaks.

Salmonella Enteritidis has been shown to contaminate the contents of the intact egg, as a result of ovarian infection in the hen. The hens themselves may be infected *in ovo* or by contact with infected mice or a contaminated environment. In response to the *S.* Enteritidis epidemic, many states adopted Egg Quality Assurance Programs, a series of control measures including screening flocks for infection, pasteurizing the eggs from infected flocks, better rodent control in henhouses, and a requirement for refrigeration of eggs during transport and distribution, so that a small number of contaminating *Salmonella* do not have the opportunity to multiply. These measures may explain the recent decline in *S.* Enteritidis infections in states where these measures were adopted, especially in the northeast and the mid-Atlantic region, where they were first pilot tested.[139] At the same time, hospitals, nursing homes, and restaurants are switching from shell eggs to pasteurized eggs and traditional recipes that use raw egg, such as homemade ice cream, eggnog, and Caesar salad, are being rewritten. Eggs that are pasteurized in the shell are now commercially available.

Licensing and inspection of food-service establishments, particularly when coupled with food-handler education and certification, is an integral part of the public health effort to prevent foodborne illnesses of all sorts, including salmonellosis. Educating consumers themselves is a constant effort, requiring the cooperation of the food production and retailing industries, the education establishment, and public health officials.

Many control measures are implemented to prevent person-to-person transmission and contamination of food by ill food workers. The potential for these types of transmission makes it prudent to exclude from work food handlers or healthcare workers with acute *Salmonella* enterocolitis, and convalescent persons in sensitive occupations who continue to shed the organism are often excluded until stool cultures no longer yield *Salmonella*. The risk posed by the entirely asymptomatic shedder is low and does not justify routine periodic stool cultures of food handlers or healthcare providers. Nosocomial salmonellosis can be controlled by taking routine precautions to prevent transmission of enteric organisms from patients with acute salmonellosis, including strict hand washing and other basic tenets of hospital infection control.[67]

Reptile-associated salmonellosis also has required specific control measures. The ban on the sale of small pet turtles in 1975, following unsuccessful efforts to educate the turtle-owning public in methods to reduce risk, led to a dramatic decrease in the isolation rate of turtle-associated serotypes.[23] However, outbreaks associated with small turtles continue to occur, possibly through exceptions to the federal prohibition.[140] It is unclear whether efforts to educate the public about the risk of iguana-associated salmonellosis will provide sufficient prevention.[89]

10. Unresolved Problems

There are many control points in the chain of transmission of *Salmonella*. However, it is difficult to achieve coordinated control efforts among the many industrial, professional, and regulatory groups involved. Salmonellosis will continue to be an important public health problem in the industrialized world and an increasing problem in developing countries. Although the pathogen has been well known for more than 100 years, fundamental questions remain unanswered. Microbiological issues in need of further study include clarifying the mechanisms of virulence, which may ultimately permit the successful development of vaccines. More rapid and sensitive means of detecting the organism in foods or the food production environment are needed if programs of food safety that depend on bacteriologic monitoring are to be widely implemented.

Several important clinical issues are unresolved. The risk factors for invasive infection in infants, particularly meningitis, are poorly defined and the use of antimicrobials to treat *Salmonella* enterocolitis in infants to prevent invasive infections is presently unproven. The paradoxic and important ability of the organism to persist in the individual who is treated with antimicrobials, even when the organism is sensitive to those antimicrobials in vitro, needs to be explained. Developing a treatment that would eliminate long-term carriage would be of benefit. Antimicrobial resistance of strains isolated from humans in the United States poses clinical challenges for the treatment of invasive infections and increases the risk that resistant salmonellosis will complicate the therapy of other infections. The problem of antimicrobial resistance would benefit greatly from a rational approach to

defining the choice and indications for use of antimicrobials in animal husbandry. Invasive infections are likely to be an increasing clinical problem, as the population ages and AIDS remain prevalent.

Unresolved public health issues include the need to incorporate population-based estimates of the burden of salmonellosis with information about the sources of these infections identified in outbreak investigations and sporadic case–control studies. In this way, the relative contributions of various foods, such as poultry products and produce items, and nonfood exposures, such as reptile pets, to the overall problem can be calculated. To take full advantage of opportunities provided by detection of outbreaks through surveillance enhanced by molecular subtyping, improved methods to rapidly investigate widely distributed outbreaks are needed. These outbreaks are challenging as they are often related to low-level contamination of a commercial food item. Expanded international collaboration can help identify and control foodborne sources of infection in our increasingly globalized food supply. Effective prevention strategies need to be demonstrated for salmonellosis in infants and HIV-infected individuals. Data obtained at slaughter could be used to target control efforts in the source flocks or herds. Better understanding is needed of the complex ecologies that may link animal reservoirs to plants that we eat. Reducing the contamination of our food supply will require a continuing effort to identify specific critical control points at the farm, the packing shed, the slaughterhouse and rendering plant, and the food-processing factory and to implement cost-effective control measures.

CHAPTER 33

Shigellosis

Gerald T. Keusch

1. Introduction

Shigellosis is an acute, infectious, inflammatory enteritis of humans and, on occasion, subhuman primates. Because it is often clinically manifested by the dysentery syndrome (a triad of frequent small-volume bloody-mucoid stools, abdominal cramps, and tenesmus) it is often referred to as bacillary dysentery to distinguish this infection from amoebic dysentery. However, watery diarrhea without blood or mucus is common in infection due to all *Shigella* species and may be the only clinical manifestation of infection. In addition to these clinical presentations, there are a myriad of non-intestinal manifestations described in shigellosis, some common and some rare, that without doubt qualify the organism as a protean pathogen. The objective of this chapter is to present the salient features of shigellosis in sufficient detail to understand the spectrum of the disease and its distinctive epidemiology.

2. Historical Background

Dysentery has long been clinically recognized. The classic syndrome is depicted in the Old Testament, and it is mentioned in the descriptions of war, so common in our history, from Thucydides in the Levant to Montgomery at the Battle of El Alamein and more recently in the Persian Gulf and Iraq wars.

There are two principal causes of the dysentery syndrome – *Shigella* species and *Entamoeba histolytica* – and a number of minor causes, including *Salmonella* and *Campylobacter*. Under circumstances of epidemic dysentery, *Shigella* is more likely to be the agent involved, while sporadic disease in adults associated with liver involvement is probably due to *E. histolytica*. However, in individual patients, the specific etiology of the syndrome can be determined only by laboratory investigation. This first became possible after Losch described *E. histolytica* and demonstrated its virulence in dogs in 1875, and Councilman and Lafleur reported the anatomic criteria for the diagnosis in humans in 1891. However, the problem of assigning etiology to cases of dysentery in which neither the organism nor characteristic histology was present remained. The loop was closed in 1898 by Dr. Kioshi Shiga,[1] who isolated the organism now known as *Shigella dysenteriae* 1 (Shiga's bacillus) from the stools of patients with epidemic dysentery in Japan during a particularly widespread (almost 90,000 cases) and severe (25% mortality) outbreak at the end of the 19th century. Shiga also confirmed the relevance of this organism by demonstrating the presence of specific serum agglutinins in individuals convalescent from the disease but not in the healthy or in patients with other diseases. In fact, the identical organism had been reported a decade earlier by Chantemesse and Widal as the cause of nonamoebic dysentery, but the description was less complete and lacked the epidemiological proof of Shiga's study, and so it is the Japanese microbiologist who is honored in the genus name. Two years later, Shiga's results were confirmed by Flexner in the Philippines and by Kruse in Germany.

Soon thereafter, Kruse isolated a similar but serologically distinct organism during an outbreak of "asylum dysentery," an epidemic disease common in institutions for the mentally ill, which he called *Bacillus pseudodysentery*. Identical organisms were soon described by Flexner, Strong, Musgrave, and Castellani, who suggested the name *B. paradysenteriae* instead. Todd referred to this same strain as *B. dysenteriae* Flexner, and to clear the confusion the name *S. flexneri* was ultimately adopted. A third species was defined by Duval, Castellani, and Kruse,

who found a serologically distinct, late lactose-fermenting *Shigella*, which Kruse originally called *B. pseudodysenteriae* type E. To honor the subsequent extensive work of Sonne on Kruse's type E organism, the name was first modified to *B. dysenteriae* Sonne and then shortened to *S. sonnei*.

The final stage in classification of shigellae began in 1929 with Boyd's studies in Bangalore, India, of non-lactose-fermenting, mannitol-positive organisms resembling *S. flexneri* that were not agglutinated by *flexneri* antisera. Boyd showed that there were distinctive serological reactions with homologous antisera to the inagglutinable Flexner group, and on this basis such strains were classified together as *S. boydii*. By 1938, then, fully 40 years after the first complete description of the prototypic organism, *S. dysenteriae* 1, the four species of *Shigella* were defined (*dysenteriae* [10 serotypes], *flexneri* [6 serotypes], boydii [15 serotypes], and *sonnei* [1 serotype but multiple colicin types]).

At the beginning of the 20th century it was commonly believed that pathogenic bacteria exerted their effects via toxins, following the example of tetanus and diphtheria. Investigators therefore looked for and found that cell-free culture supernates of Shiga's bacillus, but not the other species, were toxic to animals, causing a characteristic limb paralysis followed by death in certain species.[2] This toxic activity was therefore called Shiga neurotoxin. Over the next 50 years, the neurotoxic material was clearly shown to be a protein distinct from lipopolysaccharide and, when partially purified, to be one of the most potent known poisons. From the time of its discovery, however, neurotoxin remained a biological activity in search of pathogenetic relevance until 1972 when neurotoxin-containing cell-free preparations from recent epidemic isolates of Shiga's bacillus were shown to be enterotoxic as well, capable of inducing both fluid secretion by rabbit small intestine and an inflammatory enteritis resembling the colitis of human dysentery.[3] Although this finding suggested the importance of the toxin in pathogenesis of the intestinal phase of shigellosis, the chromosomal gene for Shiga toxin (Stx) is restricted to *S. dysenteriae* 1 and it is considered to be a salient accessory factor involved in pathogenesis of the particularly severe disease associated with this species. However, this may change as the closely related Stx-1 gene present in a naturally transferable temperate phage has been identified in *S. dysenteriae* 4 causing human illness.[4] Other enterotoxic proteins have been identified in non-dysenteriae 1 strains isolated from diarrhea patients, indicating a potential role in pathogenesis.[5] Certain serotypes of *Escherichia coli*, for example O157:H7, produce toxins closely related to Shiga toxin and play a role in pathogenesis of hemorrhagic colitis and hemolytic–uremic syndrome.[6]

3. Methodology

3.1. Sources of Mortality and Morbidity Data

It is difficult to accurately determine morbidity or mortality rates due to shigellosis, except during epidemics or in microbiologically proven hospital series. There is first of all a "numerator problem" to identify shigella infections because in the absence of bloody diarrhea or frank dysentery the clinical manifestations of shigellosis are indistinguishable from other bacterial or viral diarrheas. Without laboratory confirmation the etiology of the illness cannot be determined, unless the case is part of a cluster of clinically related illnesses, as in a common-source or a day-care center outbreak, at least one of which is laboratory confirmed. The laboratory diagnosis of an individual case currently depends on good microbiological technique. Unfortunately certain media commonly used for isolation of enteric pathogens are inhibitory to the growth of shigellae. In addition, prior treatment with antibiotics may prevent growth of the pathogen and render cultures unreliable. Good laboratory practice and the use of multiple media are essential to maximize yields. Cultures taken in the field are often transported to a laboratory for processing using a transport medium. However, shigellae do not survive well in certain commonly used transport media, such as Cary–Blair, resulting in underreporting. Second, there is also a "denominator problem," to identify patients at risk of shigella infection. Not only are some age groups less susceptible, but also asymptomatic and mild infections may occur more frequently than previously suspected.[7] *Shigella* infection is most often identified in patients, usually children, who either have the dysenteric or bloody diarrhea forms of the illness or complications, such as seizures. More mildly affected patients, particularly those without grossly bloody stools, are usually treated symptomatically and specific etiology is not determined. The problem of underdiagnosis is even more pronounced in many developing countries, where access to health care facilities is limited and laboratory services are, as a general rule, not available.

Available data generally come from three sources: (1) hospital-based reports, (2) etiologic investigations of diarrhea in the community setting, and (3) national surveillance. The first source will miss most of the disease in the community. The third, such as the national surveillance system maintained by the US Centers for Disease Control and Prevention (CDC), depends on multiple reporting sources based on cultures submitted to local and state health departments. This is now supplemented by an active surveillance for foodborne pathogens known as FoodNet, carried out in 10 states in the US with a catchment area of some 44 million people.[8]

Community studies of the second sort provide the most reliable estimates of morbidity or mortality; however, these data are usually time and place specific and are not necessarily applicable universally.

3.2. Surveys

Both bacteriologic and serological methods have been used in prospective community-based surveys of the incidence and prevalence of *Shigella* infection. However, bacteriologic surveys can underestimate the true infection prevalence because the stool sample may be inadequate or poorly handled so that organisms die before they can be cultured on appropriate media or because patients are sampled either too late in the course of their illness or after antibiotic therapy has been initiated.

A variety of serological methods have been employed for detecting both acute infection as well as evidence of past infection, but their usefulness is limited because there can be serological cross-reactivity between *Shigella* and other genera of bacteria as well as between different serotypes of *Shigella*. In addition, titers may wane rather quickly after infection. Serotype-specific enzyme-linked immunosorbent assays (ELISAs) have been incorporated into test kits which have been validated in the field and appear to be sensitive and specific.[9] A new dipstick version has recently been described for *S. flexneri* 2a.[10] Multiplex PCR assays for shared *Shigella* virulence traits, such as invasion plasmid antigens or other outer-membrane proteins or toxins, have been developed, but their utility for diagnostic or epidemiological purposes has not been fully explored.[11]

3.3. Laboratory Diagnosis, Isolation, and Identification of the Organism

Shigellae are slender, gram-negative, nonmotile rods. They are members of the family Enterobacteriaceae and tribe Escherichia and are closed related to *E. coli*. Routine isolation and identification of *Shigella* species involve the use of selective bacteriologic media that spotlight certain biochemical properties of the genus and allow a presumptive microbiological diagnosis. Identity can be quickly confirmed by the use of serological agglutination reactions, employing group-specific anti-O (somatic) antigen sera. Unfortunately, many of the commercially available typing sera are of poor quality, being too dilute or too cross-reactive to identify group- or type-specific antigens.[12] Even so, the grouping sera are reasonably good for *S. dysenteriae* 1, *S. flexneri* (except *flexneri* 6), and *S. sonnei* bearing form I antigen, which are the most important isolates to identify in the United States.

Feces is the most frequently submitted specimen for isolation of *Shigella*. Feces is a complex ecosystem of many different organisms, therefore laboratory isolation uses special media with two purposes in mind: (1) to suppress the growth of the usual nonpathogenic normal flora that might numerically overwhelm and obscure the growth of *Shigella* and (2) to dramatically contrast the colonial appearance of the possible pathogen with that of the common commensal so that suspect colonies may be picked for further study. This is accomplished by inclusion in the media of substances inhibitory to the growth of nonpathogens and a dye indicator system to detect rapid fermentation of lactose, since all shigellae are unable to perform this reaction, while most commensals can. A variety of media have been developed for this purpose; the most successful and currently used are MacConkey's bile salt, xylose–lysine–deoxycholate (XLD), Hektoen enteric (HE), and tergitol-7-triphenyl tetrazolium chloride agars. These media permit the growth of all *Shigella* species reasonably well, are inhibitory to normal flora, and clearly distinguish the lactose-negative organisms by color reactions. *Salmonella–Shigella* (SS) agar is far too inhibitory to shigellae, especially to *S. dysenteriae* 1, to be recommended for general use, particularly if only one differential medium is used.[13] Indeed, use of several media is highly recommended to maximize the yield of positives. When the number of organisms in the sample is small, isolation may be facilitated by brief enrichment in broth inhibitory to nonpathogens, such as Hajna's gram-negative broth. After 6–8 h of incubation of the sample in broth, the resulting growth is streaked onto the same differential media used in direct isolation.

Three technical details should be followed to minimize the number of false-negative cultures: (1) whenever possible, inoculate from a stool sample, rather than a swab, selecting blood-tinged mucus plugs as the source of culture; (2) if a swab is to be used, be certain that it passes beyond the anal sphincter; and (3) if there is to be any appreciable delay in processing the sample, place it in buffered glycerol–saline-holding medium.[14] Some evidence suggests that extending incubation of plates to 48 h can increase the yield of positives by almost 5% with no additional cost and minimal additional technician time.[15] In endemic regions of the world this may be a useful approach to specific diagnosis.

Lactose-negative colonies are picked to a medium such as triple sugar iron (TSI) agar, which allows confirmation of the lactose-negative phenotype and detects glucose fermentation and lack of motility, which are additional properties of shigellae. Both the agar surface (slant) and the butt are inoculated with the colony to be tested, to achieve aerobic and anaerobic conditions, respectively. In the butt, fermentation of glucose results in a pH change and a change in the

color of the phenol red indicator to yellow (acid) but without gas bubbles, while on the slant, the failure of the organism to use lactose (or sucrose, which is also contained in TSI) precludes sufficient drop in pH to change the pink (alkaline) color. TSI also distinguishes the non-lactose-fermenting enteric pathogens in the genus *Salmonella*, for which, in contrast to *Shigella*, a black reaction product is deposited due to H_2S formation. The presumptive diagnosis is then confirmed by serological agglutinations using group-specific antisera. More thorough biochemical studies can be done, but this is rarely necessary for clinical needs, and the criteria enumerated above, included in standard schemata for the identification of Enterobacteriaceae, are sufficient for diagnostic purposes.

4. Biological Characteristics of the Organism

The ability to invade epithelial cells has been considered the single most important characteristic of *Shigella* mediating its characteristic pathogenesis. Studies over the past decade have shown that invasiveness per se is just one characteristic of a set of traits that allows the organism to enter the host cell, then multiply, spread within the infected cell and directly from cell to cell, and most importantly for virulence to activate a number of cell-signalling and cytokine pathways. Ultimately these events kill the contiguously infected cells and result in mucosal ulceration.[16] The cell biology of *Shigella* is a highly complex and exquisitely interactive process between microbe and host, and in contrast to previous interpretations, cell death is the response to and not the cause of inflammation. These microbial properties are enlisted in a sequential manner during infection and are dependent on multiple virulence genes encoded on both the chromosome and a large 120- to 140-MDa plasmid present in all virulent *Shigella* and the phenotypically similar enteroinvasive *E. coli* (EIEC).[17] These virulence genes are, in turn, under the control of multiple regulator genes.[18] Once invasion of a single host cell has occurred, the entire process from invasion by a process analogous to phagocytosis, escape from the phagocytic vesicle, intracellular multiplication, cell-to-cell spread, and death of the newly infected cell can occur without exposure of the organism to the external milieu. In this manner, *Shigella* secures a secure ecological niche for itself, sequestered away from host antibacterial immunity. This protected niche is one of the factors permitting establishment of infection in a significant number of adults challenged with as few as 100–200 viable *Shigella*[19] (Table 1). The tiny infective dose, in turn, permits effective contact spread from host to host without the need for enrichment growth in some vehicle such as food or water.

Table 1. Infectious Inoculum in Experimental Shigellosis in Normal Adult Volunteers[a]

[b] Estimated number of bacteria given in oral inoculum, suspended in 30 ml of milk.

4.1. Invasiveness and Intercellular Spread

It is now clear that invasion of host cells by virulent *Shigella* occurs within a host cell membrane-bounded vesicle by "non-professional" phagocytic cells.[16] Invasion must be followed by escape from the vesicle to the cytoplasm where multiplication of the organism is possible, spread within each host cell, and invasion of adjacent cells, since interruption of any of these stages renders the organism avirulent. The process has been arbitrarily divided into four stages, including (1) entry into the host cell, (2) vesicle lysis and bacterial growth, (3) intra- and intercellular spread, and (4) death of the host cell. Distinctive genes are required for each step, and while this model for virulence has been developed largely on the basis of studies of *S. flexneri* strains, the more limited number of studies with other *Shigella* serotypes and the biologically similar enteroinvasive *E. coli* (EIEC) indicate the same mechanisms are involved.

4.1.1. Invasion. Earlier studies of cell invasion were carried out in non-intestinal tissue culture models and demonstrated that *Shigella* invade directly across the apical membrane of the host epithelial cells. When more relevant models are used it is clear that the initial site of invasion from the intestinal lumen is probably the antigen-sampling M cell rather than the enterocyte.[20] Inflammatory reactions in the lamina propria result in an inpouring of neutrophils which migrate between intestinal epithelial cells to the lumen. This opens up the intracellular tight junctions which, in turn, allow large numbers of *Shigella* to reach the basolateral membrane of the enterocyte which can be directly breached by the organism, markedly accelerating the process.

Organisms enter the cell within a vesicle formed from host cell membrane, initiated by at least three surface proteins of the microbe called invasion plasmid antigens (IpaB, C, and D). These proteins are encoded by a plasmid operon common to all invasive and virulent shigellae and EIEC and are transported to and inserted in the outer membrane of the organism under the control of two regulatory gene sets, *mxi* (membrane export of Ipa) and *spa* (surface presentation of invasion plasmid antigens). Ipa proteins lead to complex changes in the cytoskeleton of the host cell that underlie vesicle formation and bacterial entry.

4.1.2. Vesicle Lysis and Intracellular Multiplication. To be virulent, *Shigella* must also rapidly escape the vesicle to reach the cytoplasm of the host cell. Lysis of the vesicle has been associated with a temperature- and pH-dependent contact membrane lytic activity, sharply increased at the acid pH achieved within phagocytic vesicles.[21] The molecular basis for vesicle lysis appears to reside in the Ipa proteins involved in bacterial invasion since nonpolar inactivation mutants of IpaB, C, or D are inhibited in both entry and lysis of the vesicle. Intracytoplasmic multiplication of *Shigella* begins soon after vesicle lysis and if inhibited by a variety of methods the organism loses virulence.

4.1.3. Intra- and Intercellular Spread. Although *Shigellae* do not have flagella and are therefore nonmotile, they must move within the host cell cytoplasm to reach the plasma membrane to be in a position to invade adjacent cells from their intracellular niche. An elaborate mechanism allows the organisms to use the host cell cytoskeleton to accomplish this, via the plasmid-encoded protein IcsA.[22,23] IcsA is expressed during bacterial division at the back pole of the organism, defined in terms of its subsequent direction of movement. IcsA initiates localized actin polymerization, and interactions with other host cell proteins, such as plastin, result in actin cross-linking and contraction, which provide a forward propulsive force. This so-called actin motor is energized by ATP also generated by IcsA, which is an ATPase that is regulated by cyclic nucleotide-dependent host cell protein kinases that phosphorylate IcsA.[24] Bacteria defective for phosphorylation demonstrate enhanced microbial spread, whereas protein kinase inhibitors block host cell invasion. The process of cell-to-cell invasion is initiated when *Shigella* reach the host cell membrane where they create long finger-like protrusions, still membrane bounded, into the adjacent cell. These subsequently fuse with the plasma membrane of the second cell allowing the organism, now within a double membrane vesicle, to reach the cytoplasm of the newly invaded cell. Lysis of this vesicle again places the bacterium in the cytoplasm of the newly invaded cell.

4.1.4. Cell Death. The end result of invasion and cell-to-cell spread is host cell death, which results in the characteristic ulcerations of bacillary dysentery, but whether or not epithelial cell death is important for pathogenesis remains uncertain. There is good evidence that invasion of macrophages in the lamina propria by *Shigella* results in cell death by a process of apoptosis, [25] and this leads to the release of cytokines and other mediators that play a role in orchestrating the inflammatory response. IpaB is essential for this phase of pathogenesis, since strains with mutational inactivation of IpaC or D but still expressing low levels of an inserted *E. coli* hemolysin to allow escape from the phagocytic vesicle are able to induce apoptosis whereas an IpaB mutant does not.[26]

4.2. Acid Resistance

Impaired gastric acid secretion, from whatever cause, increases the risk for *Shigella* infection. This is because gastric acid is an effective barrier for acid-sensitive organisms, reducing the number of viable organisms entering the more hospitable small intestine. The ability to resist acid pH is a non-specific but efficient accessory virulence trait. Acid resistance helps to explain one of the unique characteristics of *Shigella* pathogenesis, the ability to cause infection and illness with a very small inoculum.[27] This is so important to *Shigella* lifestyle that more than one mechanism has been identified, including a glutamate-dependent mechanism regulated by a stationary growth phase sigma factor encoded by *rpoS* and a glutamate-independent mechanism controlled by the iron-regulated *fur* gene.[28]

The acid resistance phenotype is growth phase dependent, expressed when the organisms reach late log and stationary phase in an acid pH environment, conditions present in the large bowl.[29] This is ideal, as the organisms become acid resistant as they enter the environment via the feces and thus are already programmed to survive stomach acid when ingested by a new susceptible host. There is a trade-off, however, at least in vitro, as acid-resistant bacteria have a reduced capacity to invade mammalian cells. Acid resistance is lost as the organisms encounter neutral to alkaline pH, as they do in the small bowel, which restores their ability to rapidly multiply.

4.3. Other Virulence Determinants

Soluble proteins, such as iron-binding siderophores, provide an advantage to *Shigella.* Iron uptake is essential for bacterial growth, and such proteins are required to bind and transport iron into the bacterial cell. While there appears to be no difference in growth or invasive capacity between

siderophore-positive or -negative organisms in tissue culture, this is an environment in which iron is provided and is readily available. In contrast, in vivo free iron is virtually completely protein bound and functionally unavailable, and the kinetics of infection with siderophore mutants is delayed, indicating the importance of iron uptake mediated by siderophores.[30]

Some evidence suggests that superoxide dismutase (SodB) produced by *Shigella* promotes microbial survival and so enhances virulence by blocking the bactericidal effects of host-derived reactive oxygen radicals.[31] A *sodB S. flexneri* mutant is extremely sensitive to oxidative stress and is readily killed by macrophages and neutrophils and has been shown to be attenuated in certain animal models of virulence.

The specific structure of the O side chain of the somatic antigen of lipopolysaccharide (LPS) endotoxin may also affect virulence in some *Shigella* strains. Conjugal transfer of *E. coli* somatic antigen 8 into *S. flexneri* 2a renders the organism avirulent.[32] However, if *E. coli* O-25 antigen is used instead in identical experiments there is no change in virulence. The latter has been shown to resemble *S. flexneri* 2a somatic antigen in its high mannose content. Rough *Shigella* lacking O side chains invade and multiply intracellularly but do not spread from cell to cell, and they too are avirulent in vivo. Moreover, they do not cause disease in humans accidently infected in the laboratory, in contrast to smooth (O-antigen complete) strains.[33] Lack of virulence of rough mutants appears to be, in part, the failure to transport and correctly localize IcsA in the bacterial cell outer membrane.[34] Mutations in the LPS core region biosynthetic pathway delay cell-to-cell spread in vitro as well as reduce the extent of the inflammatory mucosal reaction in vivo.

4.4. Toxins

Shiga toxin (Stx), a cytotoxic protein toxin made by *S. dysenteriae* 1, is lethal when injected into certain species of mammals and is of the same order of potency as botulinum

Table 2. Selected Recent Surveys of Antimicrobial Resistance of *Shigella* Species

and tetanus toxins.[35] Stx is not an essential virulence factor, for just one species, *S. dysenteriae* type 1, produces the toxin. However, Stx-positive wild-type *S. dysenteriae* cause a more severe illness than toxin-negative strains in both rhesus[36] and human volunteers.[37] Shiga toxin-producing *Shigella* and *E. coli* can result in hemolytic–uremic syndrome and thrombotic thrombocytopenic purpura, whereas toxin-negative strains do not.[38] These three toxins, Stx and *E. coli* Stx-1 and Stx-2, represent a closely related family of heterodimeric proteins composed of one enzymatically active A subunit and a cluster of five identical B subunit monomers that mediate binding of toxin to target cell receptors. All share the same enzymatic specificity and inactivate 28S rRNA of the mammalian ribosome and block protein synthesis.[39] In rabbit ileum Stx inhibits the synthesis of brush border enzymes, including lactase, sucrase, and alkaline phosphatase, and results in blunted villi with increased numbers of inflammatory cells in the lamina propria and extrusion of epithelial cells into the lumen.[40] The B subunit pentamer for all of these toxins binds to the same receptor, a glycolipid terminating in a galactose-α1→4-galactose disaccharide.[41]

Two other protein toxins designated *Shigella* enterotoxin (ShET)-1 and -2 are present in some strains, the former exclusively in *S. flexneri* 2a.[42] These toxins alter electrolyte transport and cause net fluid secretions in animal models. Neutralizing antibody is present in humans, indicating that they are produced in vivo. Deletion of the genes for the ShET toxins in a potential vaccine strain of *S. flexneri* 2a further attenuates the organism in human volunteers, suggesting a clinical role for these proteins.[43]

4.5. Antimicrobial Resistance

Resistance to antimicrobial agents commonly used in the treatment of shigellosis is a major problem in developed and developing countries. Increasing resistance to ampicillin and trimethoprim–sulfamethoxazole (T-SMX), the least cost drugs of choice for the treatment of drug-susceptible shigellosis, has rendered these drugs virtually useless.[44] Nalidixic acid, a first-generation quinolone, was initially effective and used in developing countries for drug-resistant *S. dysenteriae* type 1 and *S. flexneri* infection but is now ineffective because of acquired resistance. The second-generation fluoroquinolone ciprofloxacin has become the drug of choice, but until generic versions became available was an expensive option for many developing countries. However, strains with decreased susceptibility are beginning to appear.[45] Ceftriaxone and azithromycin are alternative, albeit expensive, choices, but unfortunately resistance is also emerging (Table 2). Part of the problem of emerging resistance is the frequency with which antibiotics are inappropriately used.[46]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In 1986, it was estimated that 140 million cases and 576,000 deaths occur annually due to *Shigella* infection in children under 5 years of age, even excluding data from China.[47] In 1999, Kotloff et al. conducted a comprehensive review and estimated that there were more than 113 million episodes yearly in children under 5 years in developing countries, or 0.2 episodes of bloody diarrhea per child per year, with as many as 600,000 deaths.[48] These estimates are problematic because routine surveillance does not usually record bloody diarrhea separately from watery diarrhea, nor are culture techniques often employed. This may have the effect of reducing the perceived incidence of shigellosis, especially because grossly bloody diarrhea is just one of the manifestations of infection. It is not surprising, then, that a recent thorough and prospective culture-based surveillance project in six Asian countries documented a higher incidence of *Shigella* infection than previously believed, with an incidence of 1,320/100,000 in children under 5 years.[49] Overall, a *Shigella* species was isolated from 5% of diarrheal stool samples, an incidence of 210/100,000 in subjects of all ages. These data, well documented and collected, revealed that two thirds of the isolates were *S. flexneri*, except in Thailand where *S. sonnei* accounted for 85% of the strains recovered. In addition, one third of a sample of culture-negative stools was positive for the IpaH antigen of *Shigella*, suggesting even higher rates of infection than identified by culture methods, most likely due to prior antibiotic use and/or suboptimal microbiological technique. Shigellosis continues to be a major problem in the developing world, especially in children under 5 years of age.[50] Given the continuing drop in estimated diarrheal mortality to 1.5–2.5 million per year during the 1990 s, associated primarily with the increasingly widespread use of oral rehydration therapy (ORT), and the limited impact of ORT on *Shigella* lethality, a substantial portion of the deaths remaining after subtraction of the 600,000 deaths estimated to be due to rotavirus are probably due to *Shigella.*[51] Progress in the control of shigellosis in the developing world has, as a result, lagged behind in the control of watery diarrhea.

In the United States, CDC estimates that there are still some 450,000 persons infected with *Shigella* spp. annually, with over 6,000 hospitalizations.[52] Endemic isolation rates for all *Shigella* spp. derived from the CDC's

national laboratory-based surveillance system has approximated around 6 per 100,000 between 1967 and 1988, although there were periods of increased endemicity, when rates increased to 9–10 per 100,000.[53] Rates since then have dropped slightly, with an annual incidence of 5.6 cases per 100,000. There continues to be year-to-year variation, with a peak of 7.6/100,000 in 1993 and a low of 3.7/100,000 in 1999. In addition, case rates are not uniform across the United States, ranging from 10 cases per 100,000 in the Western states to 3.9 cases per 100,000 in the Northeastern states. The downward trend in the United States was more apparent during the years 1998–2002, when incidence dropped to 3–4/100,000. These trends are confirmed by data generated from the CDC's Foodborne Diseases Active Surveillance Network, FoodNet. Compared to the baseline period, 1996–1998, the isolation of *Shigella* decreased by 35% in 2006.[54] Based on proven isolations, the proportion of all samples positive for *S. sonnei* increased from 64% in 1989 to almost 84% in 2002. When separated by species, the overall reduction in shigellosis during the surveillance period has been primarily due to a decrease of 64–83% in the frequency of non-*sonnei Shigella* species, particularly *S. flexneri*. Compared with 1990, *Shigella* isolation rates at the millennium were lower in urban, semiurban, rural, and low-income counties, and most dramatically in counties with a relatively high proportion of Native American or African-American residents. As in the past, the overall isolation rate in children under 5 years (20.6/100,000) was five times greater than in adults over 20 years of age (<4/100,000).

There are several population groups in the United States at greater risk of shigellosis than the general population. These include Native Americans, who, in addition, are more commonly infected with *S. flexneri* than the rest of the American population. The developmentally disabled and mentally retarded are also at increased risk because of the difficulty in controlling fecal contamination in their environment. This problem has historically been referred to as "asylum dysentery." Just a few decades ago, as many as 10% of long-time residents of residential schools were infected with *Shigella* at any time, and new admissions had an amazing incidence of 37,000 per 100,000. Long-term, intermittent excretion of the organism was present in 7% of residents, due either to prolonged carriage or frequent reinfection. In New York state from 1982 to 1987, the relative risk (RR) for diarrhea outbreaks at summer camps for the developmentally disabled compared to summer camps for normal children was 8.6, and all the *Shigella* infections occurred in the former (RR = infinity).[55] Now that institutionalization is no longer the norm, other situations in which children are clustered together, such as summer camps, represent the greatest challenge. Finally, and for the same reasons, all children in day-care centers have a higher incidence of shigellosis.[56] With the increase in the number of children in day-care facilities in recent years, these centers are playing an increasingly important role in transmission of the disease in the United States. In prospective studies in some centers, the incidence of culture-confirmed shigellosis has approached 7,000 per 100,000, with secondary cases in as many as one quarter of families when a child in day care developed shigellosis. In other settings, infection was first introduced into the household by a child attending day care in 25% of affected families investigated. Of concern, multidrug-resistant *S. sonnei* is increasingly being isolated in day-care outbreaks.[57]

The prototypic *Shigella* species, *S. dysenteriae* 1, was the cause of numerous outbreaks of shigellosis throughout the world in the first two decades of the 20th century, with high morbidity and mortality.[58] Inexplicably, the prevalence of this organism dropped sharply after 1920, and various serotypes of *S. flexneri* became dominant. After World War II, *S. sonnei* gradually replaced *S. flexneri* in industrialized nations,[59] while *S. flexneri* persisted in developing countries.[60] In the first decade of surveillance by the CDC in the United States from the mid-1960 s to the mid-1970 s, the proportion of *S. flexneri* went from 60.6% in 1964 to 15.5% in 1973, while the percent isolation of *S. sonnei* rose from 38.1 to 83.6%.[61] These trends have continued to the present. From 1970 through 1994, 269,890 confirmed isolates of *Shigella* were reported to the CDC through the national surveillance system.[62] Species information was available in nearly 98% (Table 3). Isolation of *S. sonnei* exceeded that of *S. flexneri* by 3:1, and the two species accounted for over 97% of all isolates. From 1989 to 2002, there were 208,368 laboratory-confirmed Shigella infections, and *S. sonnei* accounted for 71.7%, while 18.4% were *S. flexneri*.[52]

A similar change in prevalence has been observed in Israel, where *S. sonnei* overtook *S. flexneri* as the main isolate in the 1960s.[63] Between 1986 and 1991, the proportion of *S. sonnei* increased further from 60 to 91%, while

S. flexneri decreased from 29 to 8% over the same period.[64] In regions of Israel where both westernized and nonwesternized populations live in the same geographic area, *S. sonnei* was the dominant organism among the former (73.2%), whereas *S. flexneri* continued to predominate in the latter group (66.7%).[65] In Northern Israel during the same time frame *S. sonnei* was isolated more than four times more often (74%) than *S. flexneri* (21%) in hospitalized patients, whereas the relative frequencies in non-hospitalized patients was 87 and 10%, respectively.[66] Furthermore, *S. sonnei* was recovered in 82% of hospitalized Jewish patients with a positive culture but only 60% of hospitalized Arab children, who were far more likely to be poor and live in overcrowded settings. *S. flexneri* was particularly frequent among hospitalized infants, and was associated with Arab origin, large families, and residence in agricultural settlements.

5.2. Epidemic Behavior

Engrafted on this still unexplained, changing world picture in prevalence of the four *Shigella* species has been the reappearance of worldwide epidemic of *S. dysenteriae* 1 dysentery since 1969. After many years of playing a minor role in the etiology of shigellosis in Central America, *S. dysenteriae* 1 suddenly and dramatically became the dominant enteric pathogen in 1969–1970.[67] It resulted in epidemic spread of infection, affecting adults as well as children, with the index case often an adult, and it caused a degree of severity in the disease much beyond the accustomed level. For example, in 18 Guatemalan communities surveyed, the dysentery mortality increased from 39 per 100,000 in 1968 to 170 per 100,000 in 1969 when the outbreak occurred. All age groups were affected, the youngest and the oldest most significantly. The death rate for the entire country was estimated to be 250 per 100,000, varying from 334 per 100,000 in the lowlands, where there was more crowding, to 190 per 100,000 in the highlands. The case fatality rate was also quite high in untreated patients, ranging from 8.4% of community cases to 10–15% of those hospitalized because of acute illness. This rate decreased later in the epidemic when the cause was appreciated and appropriate therapy was employed. These features are in contrast to endemic shigellosis, principally due to *S. flexneri*, and to a lesser extent *S. sonnei*, primarily affecting young children in the under 5-year-old group, with the index case in families generally a preschool or school-age child and with mortality in adults an unusual event.

Epidemic *S. dysenteriae* 1 dysentery subsequently appeared in South Asia in the mid-1970 s and in Africa in the early 1980 s. After the initial large-scale outbreaks, it has become a part of endemic dysentery, with periodic surges in incidence. For example, prospective bacteriological data from 1978 to 1987 obtained in rural Bangladesh show a dominance of *S. flexneri* between 1978 and 1982 (56–67%), a rise in *S. dysenteriae* 1 prevalence between 1983 and 1985 (45–50%), and a return of *S. flexneri* in 1986 and 1987 (55–61%).[60] Continued surveillance for *S. dysenteriae* has also revealed a change in the prevalent types, from *S. dysenteriae* type 1, the dominant serotype in 1999 (76.4%), which declined to 6.5% in 2002, while *S. dysenteriae* types 2–12 were isolated with increasing frequencies, with types 2 and 4 accounting for nearly half of the total isolates.[55]

However, wherever *S. dysenteriae* type 1 lurks in the background, the potential for epidemic spread remains a threat. When a sudden influx of nearly three quarters of a million refugees fleeing Rwanda entered into Zaire in 1994, explosive sequential outbreaks of cholera and then *S. dysenteriae* 1 occurred, with a crude mortality rate of 200–350/100,000 per day and around 50,000 cumulative deaths.[68] This was followed by widespread acute malnutrition, especially in those with a recent history of dysentery and in families without a male adult. Epidemic disease remains a possibility in many parts of the world, often in association with civil disruption and migration of large numbers of people, as occurred in Central Africa in the mid-1990s.[69]

5.3. Geographic Distribution

Shigella is worldwide in distribution. The incidence of infection in different regions will vary, of course, with the level of sanitation and exposure. *S. sonnei* has become the

main isolate in industrialized countries, whereas *S. flexneri* remains the most common isolate in developing countries. *S. dysenteriae* 1 is now endemic, and occasionally epidemic, in the poor countries of Asia, Africa, and Latin America. *S. boydii* remains relatively uncommon everywhere (<1–2%) except in the Indian subcontinent. In the United States, the highest *Shigella* isolation rates are from the Southwestern states, where the relative proportion of *S. flexneri* is higher than elsewhere in the country. This may be related to the proximity to Mexico and the cross-border flow of migrant workers. Infection with *S. dysenteriae* 1 in developed countries, and to a lesser extent *S. flexneri*, is related to travel to endemic developing countries.[70]

5.4. Seasonal Transmission

Seasonal patterns of shigellosis are common, but differ in timing around the world. In the United States peak incidence of both *S. sonnei* and *S. flexneri* infection occurs in summer and early fall, with a delay of around 6 weeks from the peak in ambient temperature in Massachusetts.[71] In both urban and rural Bangladesh, *Shigella* isolation peaks in the post-monsoon season of December and January and again in the hot, dry premonsoon period of April and May. In nearby Calcutta, India, the incidence of shigellosis is highest during the monsoon season itself, while in Calabar, Nigeria, the peak occurs during the dry season. In Egypt and among Bedouins in southern Israel peak incidence is during the early summer months of June and July. In contrast to the Bedouins, Jews with a Western lifestyle living in southern Israel experience summer and winter peaks, while in nearby Saudi Arabia a winter peak for *S. flexneri* has been reported. In Guatemala, the illness tends to peak just before and in the early weeks of the rainy season. In some locales, there is no clear seasonal peak, and cases occur all year round.

A variety of explanations, none entirely satisfactory, have been offered for the different temporal patterns and seasonal transmission observed. Explanations for summertime peaks in temperate climates include increased social activity of children when school is out of session, which may promote person-to-person transmission and perhaps longer survival of organisms in the environment, although desiccation is not good for viability. On the other hand, summertime peaks during the hot, dry season in tropical climates have been explained by decreased availability of water, making it more likely that contaminated water is used and because the limited availability of water has a negative impact on personal hygiene. Peaks before or during the rainy season have been explained, respectively, by seasonal worsening of nutritional status before the harvest and by increased contamination of water supplies due to water washing feces deposited in unsanitary manner on the ground.

5.5. Age

Endemic shigellosis is a childhood disease in both developed and developing nations, whereas epidemic shigellosis due to a newly introduced strain affects all age groups.[67] But, even where shigellosis is highly endemic, neonatal shigellosis, generally originating from an infection in the mother, is rare. This is attributed to the high prevalence of antibody in breast milk among mothers in endemic settings.[72] Breast-feeding has been shown to be protective against disease among infected infants,[73] and perhaps this is why neonatal infection is often transient and asymptomatic in developing countries but systemic and severe in bottle-fed neonates in the United States.[74] Exclusive breast-feeding also reduces the likelihood of infection through contaminated weaning foods. In countries with a high endemicity of disease, shigellosis rates increase dramatically in the 3 months following cessation of breast-feeding, with an adjusted odds ratio of 6.6 (95% confidence interval, CI = 2.19–14.6, $p < 0.001$).[75] Although so-called weanling diarrhea has traditionally been attributed primarily to the risks associated with contaminated weaning foods, the addition of food supplements while breast-feeding is maintained does not increase shigella infection rates over the first 3 months of supplementary feeding, with an odds ratio of just 1.2 for addition of food supplements if breast-feeding continues (95% CI = 0.4–3.0).

However, neonatal shigellosis in developing countries may not be as benign a problem as first believed. In a retrospective 5-year review of admissions from 1984 to 1989 to an international diarrhea treatment center in Bangladesh, 4,741 patients with culture-proven shigellosis were identified.[76] Of these, 169 (3.1%) were 3 months of age or younger, of whom 19% were neonates under 1 month of age. Records were available on 159 subjects ≤3 months of age, including 30 (18.9%) neonates, and were compared with findings in 156 children 1–10 years of age, with a mean age of 27 months. Infants were much less likely to have bloody diarrhea (17.2 vs. 57.3%), fever (32.7 vs. 58.6%), pedal edema (3.8 vs. 27.2%), or rectal prolapse (0 vs. 8.3%) on admission; however, they were significantly more likely to be moderately to severely dehydrated (59.9 vs. 31.1%) or to have abdominal distension (19.5 vs. 10.1%) or bacteremia (12 vs. 5%), and were twice as likely to die (16.4 vs. 8.2%). Multivariate analysis showed that concomitant gram-negative bacteremia, ileus, decreased bowel sounds, or severe hyponatremia or hypoproteinemia were significantly

associated with fatal outcome. Interestingly, although three fifths of the cases in each age group were due to *S. flexneri*, neonates had a significantly greater prevalence of *S. boydii* (21.4 vs. 6.3%) and *S. sonnei* (7.6 vs. 1.3%), while a smaller proportion had *S. dysenteriae* 1 (9.4 vs. 31.5%).

Shigella infection rates increase in endemic developing country settings after weaning, when poor diets and frequent infections combine to adversely affect host nutritional status. In Bangladesh, the highest incidence of Shigella bacteremia and death is in infants under the age of 1 year, and the associated risk factors are weaning and malnutrition.[77] During the epidemics of dysentery due to *S. dysenteriae* 1 in the past two decades, the very young and elderly have experienced the most severe illness and the highest mortality rates.

Prevalence diminishes after the first few years of life, with a decrease in severity of illness and a relative increase in the proportion of mild and subclinical infections. As overall prevalence of infection in the community diminishes, as in developed countries, there is an apparent shift in the age-specific peak to a somewhat older age group. In the United States, the proportion of isolates in the under 5-year-olds decreased from around 47 to 37% from 1967 to 1988, while the proportion occurring in those over 20 years of age increased from 17.3 to 37.1%, especially after 1974.[53] A further decrease to 21% of confirmed *Shigella* infections in under 5-year-olds was noted in the surveillance years 1996–1998 in the population covered by the FoodNet active surveillance system, although this age group represented only 7% of the covered population.[78] The proportional rise in shigellosis among adults was 7-fold greater than the proportional increase in the size of the US population over 20 years of age during the same period of time, and approximately three quarters of the adult patients were 20–39 years old.

5.6. Gender and Sexual Practices

Age-specific attack rates for *Shigella* infection in children and for the whole US population show no gender differences. However, women account for significantly more infections among young adults. In the United States in 2004, the percentage of infected females was significantly greater than in males in the age groups 20–29 years (64.4%) and 30–39 years (53.4%), presumably reflecting their greater contact with young children. In contrast, there is a male preponderance for *S. flexneri* infection, particularly in the age groups 30–39 years (64.6%) and 40–49 years (65.6%). This is consistent with sexually transmitted infection among men who have sex with men and with the previously reported predominance of *S. flexneri* infection in this group. [79] From 1977 to 1991 there was an increase in the median age for *S. flexneri* infection from 9 to over 20 years, peaking in 1984, and then tending downward in more recent years, without a change in the median age for *S. sonnei* infections (around 7 years). This may indicate a return to the pre-1975 trend of diminishing *S. flexneri* prevalence, perhaps reflecting changing sexual practices among this group of young men. Outbreaks of *S. sonnei* among men having sex with men have been noted in the United States, Canada, Europe, and Australia.[80,81]

5.7. Race

There is no evidence that race per se affects susceptibility to the disease. Genetic factors, such as HLA-B27 antigen, clearly predispose to joint involvement and postdysenteric Reiter's syndrome; this may explain the frequency of these complications in Scandinavia, where the prevalence of histocompatibility antigen B27 in the population is relatively high.

5.8. Occupation

Certain occupations may increase exposure to shigellae. Notable examples are the increased incidence of shigellosis in women caring for young children at home. Teachers in day-care centers are also at greater risk than the general population,[82] and theoretically, so are attendants in custodial institutions for the mentally retarded, clinical microbiology laboratory technicians, and health care workers.[83] Although at risk, the lack of a striking incidence of shigellosis among laboratory technicians and health care workers suggests that good personal hygiene and ready access to clean water for washing is effective.

5.9. Occurrence in Different Settings

Shigellosis can readily spread among individuals living in close quarters where personal hygiene and environmental sanitation are inadequate. The 1994 epidemic among refugees fleeing Rwanda is evidence of this.[84] Bacillary dysentery has been a classic problem of armies at war. When US military personnel were sent to Somalia in 1992–1993 to safeguard emergency feeding programs, the diarrheal disease rates were unexpectedly low; however, *Shigella* was isolated from 33% of those affected.[77] More recently, 20% of marines, participating in the opening of the Iraq war in 2003, with etiologically proven diarrhea were infected with *Shigella*, second only to noroviruses.[85] Another setting in

Table 5. Secondary Attack Rates Among Household Contacts of Shigellosis Patients

	Secondary attack rates	
Age of exposed	*S. flexneri*	*S. sonnei*
Child	42	42
Adult	14	20

which *Shigella* outbreaks occur is aboard ships, because close contact among people is unavoidable and common meals are taken.[86] Outbreaks are much less common on commercial airplanes, and unless there are multiple cases among an identifiable group, may be difficult to identify.[87]

Introduction of illness into the household often results in intrafamilial spread, and the family should therefore be considered an epidemiological entity in this instance. The secondary attack rate is greater in children than in adults (Table 5) and infection is more likely to be symptomatic in the young as well. Nosocomial spread of shigellosis in a newborn nursery can result in serious systemic illness, shock, and death.[88]

5.10. Socioeconomic Factors

Endemic shigellosis is associated with poverty, crowding, poor sanitation, water sources inadequate in quantity and quality, and malnutrition.[65–67, 75, 76, 89] Prevalence of *Shigella*-specific antibodies, detected with specific ELISAs for serum *Shigella* lipopolysaccharides and invasion plasmid antigens, is inversely related to socioeconomic status.[5,88] Thus, water availability, water quality, sanitary disposal of feces, and control of flies each affect the infection rate individually. Controlling flies using a simple baited trap can reduce the prevalence of shigellosis by as much as 85% (Table 6).[90] However, these factors usually occur together in impoverished populations, and in general the impact of any single intervention may be limited. Pre-existing malnutrition exerts additional adverse effects and is associated with more severe illness and sequelae.[91] Bottle-feeding young infants where malnutrition is common will considerably worsen the situation, whereas breast-feeding appears to be protective until full weaning occurs.[92]

Table 6. Efficacy of a Simple Baited Fly Trap on Shigellosis Rates in Military Camps[a]

Parameter	Intervention camps	Control camps	"P" value	% Efficacy

[a]Data from Cohen et al.[89]

6. Mechanisms and Routes of Transmission

Shigella, like the typhoid bacillus, is highly host adapted to humans and may, in addition, naturally infect a few nonhuman primates as well. For this reason, more than 99% of all *Shigella* isolates in the United States are from human sources, and the route of transmission is almost invariably traceable to an infected human. Transmission is a circle from the stool to the mouth and back to the stool again. While intervening vehicles can be involved, such as food and water, shigellosis is most frequently spread by person-to-person contact. Large numbers of shigellae (10^5–10^8) are present in stools of clinical cases, whereas healthy carriers have less than 10^3 organisms/g feces. Even under epidemic conditions, epidemiological evidence favors contact spread.[84] This is encouraged by conditions of poverty, crowding, and poor sanitation, exemplified by the situation in camps for refugees, which facilitate the transfer of the small inoculum needed to initiate the infection. Contact with a recent case of dysentery is one of the prominent risk factors in developing countries; the index case within households is most often a young child under the age of 10 years.[78] Interestingly, while the use of pit or other protected latrines may not be associated with a reduction in *Shigella* transmission (odds ratio = 0.96, CI 0.43–2.15), use of a hanging latrine in which feces are discharged directly onto the ground or into a body of water can be associated with a significantly increased risk for infection (odds ratio = 1.42, 95% CI: 1.02–1.98, $p < 0.05$).[93]

Organisms, of course, can find their way to food or water sources and thereby initiate common-source epidemics.[94,95] While *Shigella* is not the most frequent pathogen identified in foodborne outbreaks, the list of documented vehicles and settings for such common-source outbreaks has been increasing over time. Foodborne *Shigella* infection is commonly traceable to an infected food handler; raw vegetables are the most common vehicle.[9] Large outbreaks have also been traced to commercially prepared shredded lettuce, and imported iceberg lettuce was the source of an outbreak in Norway, with 110 proven cases of *S. sonnei* spread via salad bars.[96,97] Thousands of individuals in Norway and other countries were undoubtedly exposed to the tainted lettuce as well, with an unknown number of unreported cases. Newly reported and different vehicles include interesting items such as moose soup in Alaska and raw

oysters along the Texas Gulf coast.[98,99] In the latter outbreak, an infected crew member of an oystering boat may have contaminated the oyster beds, since the toilet facilities aboard the ship consisted only of 5-gallon pails that were dumped overboard directly into the harvesting area. Globalization of the food supply has resulted in outbreaks of *S. sonnei* infection in Denmark and Australia due to contaminated baby corn produced in Thailand.[100]

Any mass gathering at which centrally prepared food is served can be associated with outbreaks of *Shigella* infection, especially when toilet and hand-washing facilities are primitive or limited. For example, a large *S. sonnei* outbreak occurred in 1988 at an outdoor 5-day summer music festival, affecting over 3,000 persons.[101] Major factors in this outbreak were the large number (>2,000) of volunteer food handlers preparing communal meals, limited access to soap and running water for hand washing, and a documented small outbreak of shigellosis among the staff before the festival participants arrived. Transmission from staff to attendees likely occurred early but was amplified by a large common-source outbreak due to contamination of an uncooked tofu salad served on the last day. Onset of illness peaked 2 days later, after the festival ended.

Another large outbreak happened in 1987 at a mass gathering in a national forest, where over 50% of almost 13,000 attendees were infected with *S. sonnei* transmitted via multiple routes, including food, water, and person-to-person spread.[102] When the participants returned home further dissemination of the outbreak strain followed, with at least three additional confirmed outbreaks linked to the first by the unique antibiotic-resistance pattern, phage type, and plasmid profile of the outbreak strain. Similarly, high attack rates were documented in a foodborne outbreak at summer camps for mentally retarded and developmentally disabled persons.[103] During the same period of time, nearby camps for normal youngsters recorded no shigella outbreaks.

Surveillance for waterborne disease outbreaks associated with drinking water in the United States from 1971 to 1994 reveals year-to-year variation in the number recorded.[104] Prior to 1986 there were 20–50 outbreaks identified per year, but this number was reduced to 10–20 in the subsequent years. Many different pathogens, including bacteria, protozoa, and viruses have been isolated; *S. sonnei* is one of the most common bacterial agents. Recreational water, including pools, ponds, and lakes, can be directly contaminated by feces deposited by human or animal carriers (although this is not relevant for *Shigella*) or from sewage leaking into the water and has increasingly been implicated in shigella outbreaks.[105]

In 1991, a particularly interesting outbreak of bloody diarrhea and hemolytic–uremic syndrome due to *E. coli* O157:H7 and *S. sonnei* occurred at a lakeside park near Portland, Oregon.[106] No association with food or beverage consumption was detected; however, case–control studies strongly associated illness with swimming, especially among individuals reporting prolonged time in the water and swallowing of lake water. Although neither outbreak organism was recovered from the lake, enterococci counts indicated significant fecal contamination. A similar outbreak involving 65 persons occurred at a park pond in Michigan in 1989.[107] Increased risk was associated with swimming with the head submerged. There were no detectable defects in the park's toilets or sewage disposal system, implicating bather contamination of the waters. Waterborne transmission is not restricted to swimming in contaminated water; even wind surfing on contaminated waters can lead to infection.[108]

In developing countries, a combination of contact and waterborne spread can contribute to prolonged, smoldering epidemics that last for months rather than weeks, until the population of susceptibles is exhausted. In the Central American *S. dysenteriae* 1 epidemic of 1969–1972, waterborne spread within some communities is suggested by the clustering of cases in place and time, the presence of multiple index cases in families, and the relationship between defective water distribution and illness. However, the occurrence of the disease in widely separated places that do not share food or water supplies also indicates the likely role of the human carrier in spread. In the initial Bangladesh outbreak of epidemic *S. dysenteriae* 1 among the population of a semi-isolated coral island, the introduction of the organisms into this insular community was undoubtedly from an infected human, and the early slow spread of disease is probably explained by initial person-to-person contact. Later spread was most likely caused by contamination of water sources from the excreta of the slowly increasing number of patients, and the epidemic terminated when chlorination of water was begun.

A variation on the mechanism, but not the route, of transmission has been demonstrated in recent years among homosexual men engaging in anal–oral sex practices. Severe *Shigella* sepsis has been reported in patients with acquired immunodeficiency syndrome (AIDS).[109] Sexually transmitted shigella can be associated with simultaneous transmission of other enteric pathogens, such as *Giardia lamblia*.

7. Pathogenesis and Immunity

7.1. Pathogenesis

Shigellosis is the clinical manifestation of a complex interplay between the microorganism and the host.[16] This

process appears to take approximately 2–5 days from the initial entry of the organism via the mouth to clinical disease, based on experimental human infections with *S. flexneri* 2a and *S. dysenteriae* 1.[19] Surprisingly, the clinically more virulent *S. dysenteriae* 1 strain has a longer mean incubation period than *S. flexneri* 2a under these conditions.

A sufficient inoculum must survive gastric acidity and other intestinal defense mechanisms to initiate infection. The mechanism for acid resistance has already been discussed. Human shigellosis is clearly a colonic process that results in bloody diarrhea and dysentery. Experimental shigellosis in the rhesus monkey provides evidence of involvement of both the proximal small bowel and the colon.[110] The small bowel could be the source of or contribute to watery diarrhea in shigellosis, but this remains conjecture in humans. Organisms ultimately reach the colon where they cause an invasive bacterial colitis, resulting in the typical bloody diarrhea or dysentery of shigellosis.[111] This process is now believed to be initiated by invasion of bacteria across the intestinal M cells. When the organisms reach the lamina propria they are ingested by phagocytic cells, leading to the production of cytokines, such as interleukin 8, which initiates an inflammatory response. The subsequent migration of leukocytes between epithelial cells disrupts the tight junctions and allows large numbers of *Shigella* to reach the basolateral membrane of the epithelial cells, where they are able to invade directly into enterocytes. The subsequent contiguous spread of infection from one epithelial cell to another leads to focal areas of cell damage, ulcer formation, and bleeding and further inflammatory cell exudates into the lumen, the hallmarks of dysentery.

High levels of circulating LPS are present in patients with *S. dysenteriae* 1 infection and lower levels are common in those with *S. flexneri*, even in the absence of documented bacteremia. The frequency of endotoxemia in shigellosis suggests a broader role for LPS in pathogenesis of the disease, for example, the induction of proinflammatory cytokines. However, Shigella-induced apoptosis of macrophages, mediated by caspase-1, is itself sufficient to induce the release of proinflammatory cytokines.[112] Detectable fecal levels of certain cytokines have been reported in children with *S. dysenteriae* 1 and *S. flexneri* infection.[113,114] Although no differences in stool or serum levels of tumor necrosis factor (TNF) were observed between patients with uncomplicated infections and those with hemolytic–uremic syndrome (HUS), leukemoid reaction, or severe colitis, serum interleukin 6 (IL-6) was significantly higher in the children with complicated illness.[114] In a more elaborate study, an increase in the number of cytokine-producing cells was observed in cryopreserved rectal biopsies from adult patients with either *S. dysenteriae* 1 or *S. flexneri* infection.[115] IL-1β, IL-4, IL-10, and transforming growth factor (TGF)-β1–3 responses predominated; however, there was a universal response of all cytokines studied, including Th-1 and Th-2 agonist and antagonist cytokines (IL-1α and IL-1β, IL-1 receptor antagonist, TNF-α, IL-4, IL-6, IL-8, IL-10, gamma interferon, and TGF-β1–3). Cytokine-producing cells persisted in similar number when studied 30 days after onset of acute infection. The number of IL-1, IL-6, IFN-γ, and TGF-β-producing cells was significantly and directly related to severity of inflammation, assessed by histological criteria. These cells were also greater in patients with *S. dysenteriae* 1 infection compared to *S. flexneri* infection.

The results are consistent with quantitative observations on inflammatory cells and erythrocytes in the stool, in which patients with *S. dysenteriae*, *S. flexneri*, and *S. boydii* infection are more likely to have both large numbers of fecal leukocytes and erythrocytes than patients with *S. sonnei*, and the number of leukocytes is highest in *S. dysenteriae*.[116] It is likely that severe inflammation underlies pathogenesis of ileus and toxic megacolon in shigellosis. Further evidence for a role of cytokines in pathogenesis has been provided by experimental studies in the rabbit ligated ileal loop model, in which intravenous infusion of IL-1 receptor antagonist prior to initiation of *S. flexneri* infection within the loop dramatically decreases bacterial invasion of the tissue, and mucosal inflammation and tissue destruction.[117] Production of pyrogenic proinflammatory cytokines can explain clinical symptoms such as fever and anorexia. The severity of illness, including consequences of inflammation such as bloody diarrhea and dysentery, is directly related to the fever response.[118]

The factor(s) inciting the watery diarrhea that initiates clinical illness and predominates in milder episodes, including most cases of *S. sonnei* infection, remains uncertain. The suggestion that this is a small bowel process due to *Shigella* enterotoxins has remained an attractive hypothesis, since watery diarrhea temporally precedes bloody diarrhea–dysentery as the organisms move down the intestinal tract toward the colon. Experimental primate infections provide a cogent but not conclusive argument for a small bowel phase of symptoms and the role of enterotoxins.[110] However, neither Shiga toxin (which is not only cytotoxic but also causes net secretion across small bowel mucosa by targeting and inhibiting villus cell sodium absorption but not crypt cell chloride secretion,[119]) nor the newly described ShET toxins[42,43] (which are weakly secretory in rabbit bowel by an as yet unknown mechanism) are present in all *Shigella* spp.

Fever is typical in shigellosis and a consequence of inflammation and the production of pyrogenic cytokines.

A number of systemic complications, probably related to cytokine production, occur in shigellosis. Bacteremia, most commonly encountered in infections due to *S. dysenteriae* 1 or *S. flexneri*, occur in around 4–5% of hospitalized patients in developing countries. Bacteremias due to the common enteric gram-negative rods are detected as often as are *Shigella* and are likely the result of tissue damage. In Bangladesh, bacteremia occurs primarily in children under 1 year of age and is significantly associated with malnutrition. When the sensitivity of *Shigella* to the serum bactericidal response has been studied, *S. dysenteriae* and S. *flexneri* are the most serum sensitive rather than serum resistant, as might be expected for bacteremia isolates.[120] However, patients with *Shigella* bacteremia had a 43-fold decrease in serum bactericidal activity compared to normally nourished nonbacteremic controls. Therefore, acquired defects in host defenses, for example, diminished complement activity or impaired antibody production associated with malnutrition, seem to be the most likely explanation for the bacteremia.[121]

Leukemoid reactions occur most often in *S. dysenteriae* 1 infection, often associated with HUS, a syndrome of hemolytic anemia and renal failure secondary to microangiopathic injury of endothelial cells.[122] Shiga toxin appears to play a significant role in pathogenesis of HUS since it is associated with toxin-producing *S. dysenteriae* type 1 and Stx-1- and Stx-2-producing *E. coli*. These toxins are known to target, damage, and create a pro-thrombotic state in glomerular endothelial cells, at least in experiments in vitro, especially when endothelium is preactivated by LPS or inflammatory cytokines, which increase expression of the glycolipid toxin receptor.[123,124] Toxic megacolon is an uncommon but severe problem, reflecting extreme inflammatory colitis and may result in perforation of the gut, peritonitis, and systemic sepsis.[123, 124]

Neurological manifestations in shigellosis, most commonly seizures, have been considered a variant of febrile seizures seen in young children with rapidly rising temperature due to other causes. No specific neurotoxic factors have been identified in *Shigella*. Although Shiga toxin has long been known as Shiga neurotoxin,[2] there is no evidence of a neurotoxic effect that might lead to seizure activity. There is at present no mechanism to explain the toxic encephalopathy sometimes observed during *Shigella* infections, most commonly *S. flexneri*.[125] Among nine cases of shigellosis seen among US troops deployed to Saudi Arabia during the Gulf War of 1991, two presented with "pseudomeningitis," a previously described but uncommon presentation of *Shigella* infection, occurring especially in infants and children, and readily confused with acute bacterial meningitis.[126]

7.2. Immunity

Strong epidemiological evidence suggests that immunity to *Shigella* infections is acquired following exposure to the pathogen. First, shigellosis is primarily a childhood disease except when a new epidemic strain is introduced into a susceptible population. In contrast to endemic shigellosis, epidemics involve all age groups. Second, immunization with live oral vaccines confer protection against the strains included in the vaccine, but not for circulating strains not in the vaccine. Third, rechallenge of volunteers who previously had experimental dysentery with the same serotype demonstrates serotype-specific protection.

These observations show that type-specific immunity develops after exposure to *Shigella*, directed primarily to serotype-specific LPS antigens. No other surface or secreted microbial component has been shown to be capable of inducing protective responses, although many of these constituents are antigenic. Antibody to LPS, which may mediate this protective response, is present in humans in increasing prevalence with increasing age, and titers rise more rapidly in endemic regions of the world where infants and children are more likely to encounter the organisms early in life.[127,128] It has been suggested that serum IgG antibody, in high enough titer, may be secreted into the intestinal lumen and, if in high enough titer, may be protective in the gastrointestinal tract.[129] This is the basis for the attempt to develop new generations of systemic killed vaccines. During clinical shigellosis, serum proteins leak across the intestinal mucosa in high concentration and sufficient amounts to result in a protein-losing enteropathy.[130] The presence of IgG antibody and leukocytes in the gut exudate should, at least theoretically, contribute to antibacterial local defense responses in the mucosa and the lumen. However, the quantity of serum proteins in stool, measured by levels of α_1-antitrypsin, and the number of stool leukocytes are also related to the severity of the illness and is greater in *S. dysenteriae* 1 infection compared to shigellosis due to other species of *Shigella*.

Serum anti-Shiga toxin antibody develops in the course of *S. dysenteriae* 1 infection. Its role in host defense has not been clear, since primates immunized with toxoid develop high titers of neutralizing antibody but are not protected from oral challenge with virulent organisms. Thus, they develop classic primate shigellosis, a severe and frequently lethal diarrhea and dysentery. Pre-existing serum anti-Shiga toxin antibody, however, could protect against the systemic microangiopathic pathology resulting in HUS or thrombotic thrombocytopenic purpura in either *S. dysenteriae* 1 or Shiga toxin-producing enterohemorrhagic *E. coli* infections. Experimental studies in animals demonstrate this effect of anti-Shiga toxin antibody. Infection with ShET-1 or -2

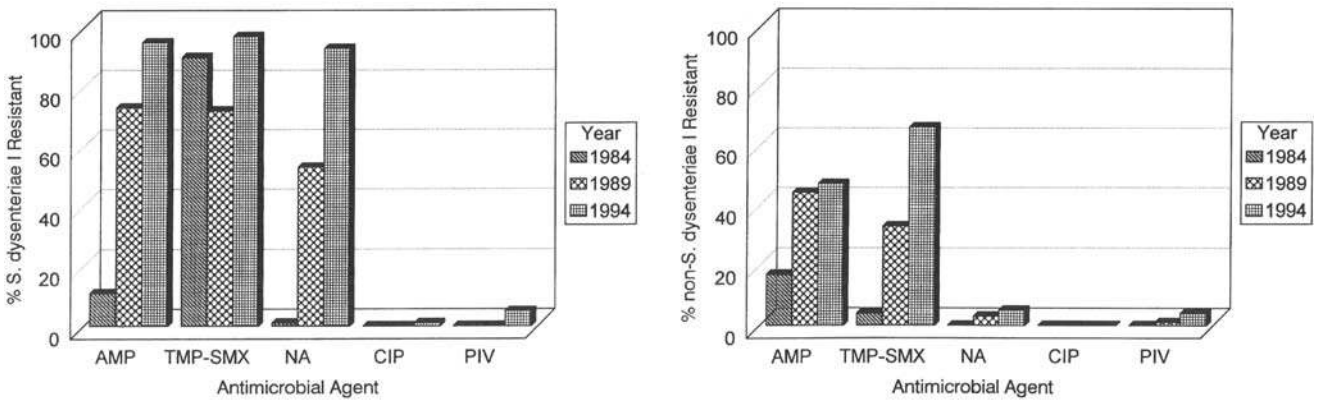

Figure 1. Antimicrobial resistance patterns of *S. dysenteriae* type 1 (*upper panel*) and other *Shigella* species, predominantly *S. flexneri* (*lower panel*), to the most commonly used drugs in Dhaka, Bangladesh, in 1984, 1989, and 1994. Following the development of resistance by *S. dysenteriae* type 1 to ampicillin (AMP) and trimethoprim–sulfamethoxazole (TMP-SMX), there was a marked increase in the use of nalidixic acid (NAL), with a marked increase in the prevalence of NAL resistance. At this time, nearly all isolates are susceptible to ciprofloxacin (CIP) and pivamdinocillin (PIV). Resistance to AMP and TMP-SMX also has increased among other *Shigella* spp., but not as dramatically, and most isolates remained susceptible to NAL, CIP, and PIV in 1994.

enterotoxin-producing *Shigella* spp. induces specific circulating antibody. The potential role of these antibodies in control of disease during acute infection or in protection from subsequent episodes is unknown at this time; however, circulating antibody may not have an impact on events at the epithelial cell luminal surface.

8. Patterns of Host Response

In fact, most clinical shigellosis is intestinal, spanning a spectrum from watery diarrhea to bloody diarrhea or dysentery. The dysentery syndrome is the most severe end of the spectrum. A clear-cut dose–response can be seen in adult volunteers experimentally infected with known numbers of bacteria (Table 1).[9] Some individuals remain asymptomatic, due to the presence of pre-existing immunity (especially in endemic regions) and the typical small inoculum size (especially in previously unexposed individuals in nonendemic regions). However, the initial postweaning exposure to *Shigella*, wherever and whenever it occurs, will more likely result in symptomatic disease. Extraintestinal manifestations involving the central nervous system (such as seizures, nuchal rigidity, meningismus, and delirium), the blood (bacteremia, leukemoid reactions, thrombocytopenia, microangiopathic hemolytic anemia), the kidney (hyponatremia, uremia), the eye (keratoconjunctivitis, iritis), and the joints (nonsuppurative arthritis) are primarily associated with *S. dysenteriae* 1 and *S. flexneri* infections and are uncommon in the United States where *S. sonnei* predominates.

Postdysenteric Reiter's syndrome (iritis, urethritis, arthritis) is usually associated with a host expressing HLA-B27 antigen and primarily a consequence of *S. flexneri* infection. Joint manifestations in such genetically prone subjects, once initiated, are often chronic and destructive. Rarely patients exhibit metastatic infection of skin, wounds, the lungs, the joints, the urinary tract, or the meninges.

8.1. Clinical Features

The initial manifestations of acute shigellosis, fever, malaise, abdominal pain, and watery diarrhea are not pathognomonic for shigella infection. Even the presence of fever cannot distinguish between *Shigella* infection and rotavirus or bacterial infections such as enterotoxigenic *E. coli,* which are often associated with low-grade fevers. Suspicion of *Shigella* increases as the disease progresses with the appearance of blood and mucus in the stools. The rectum and sigmoid area are the most severely affected; however, the entire colon may be involved in very severe infections. Inflammation and ulceration result in tenesmus and frequent passage of small-volume stools that often consist of only blood and mucus (Figure 2), characteristic of dysentery syndrome. In very severe cases, toxic megacolon and/or colonic perforation may ensue. The more virulent the organism (*dysenteriae* 1 > *flexneri* > *boydii* or *sonnei*), the more likely and more rapid is the appearance of bloody diarrhea and more frequent is progression to dysentery after onset of watery diarrhea. In fact, the course may be so rapid in *S. dysenteriae* 1 infection

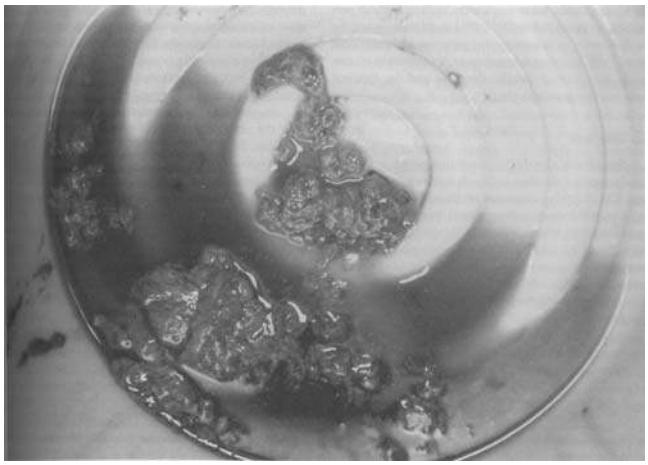

Figure 2. The appearance of the stool in most patients with shigellosis is, as shown here, a small-volume stool composed of fecal matter and bloody fluid, sometimes with mucus as well. Microscopic examination of the fluid phase reveals sheets of polymorphonuclear leukocytes and abundant erythrocytes. Passage of this type of stool is generally accompanied by abdominal cramps and tenesmus, and the three features together constitute a triad of findings that defines dysentery.

that it is hardly possible to distinguish the watery diarrheal phase at all.

In the United States, the increasing prevalence of *S. sonnei* has been associated with more mild watery diarrhea. In well-nourished subjects, the illness is generally self-limited in 5 or less days, without the need for antibiotics or other drug interventions. In the malnourished, however, *Shigella* can cause an acute fulminant infection associated with a number of complications, and continue on as a chronic relapsing disease, extending over months. At an international diarrhea treatment center in Bangladesh, where the majority of patients admitted to the inpatient unit are malnourished (mean weight for age = 59% of the NCHS 50th percentile), the fatality rate in 4,150 patients over a 5-year period was 9% (Table 7). In this population there was little difference in fatality rate for any *Shigella* species, including *S. sonnei,* suggesting that debilitation adversely affects the ability to defend against even the least virulent *Shigella* species.[89] Early deaths in shigellosis are generally due to septicemia, toxic megacolon, with or without perforation, or renal failure.[120, 123,124] Later fatalities are the result of complex interactions of infection and nutritional status.[121] In these circumstances, kwashiorkor or marasmic kwashiorkor develops and the terminal event is often another infection.

8.2. Diagnosis

Shigellosis should be suspected in febrile patients with bloody, mucoid diarrhea or the dysentery syndrome. The definitive diagnosis of shigellosis depends on identification of the organism in the stool. However, because early treatment can markedly shorten the duration and intensity of symptoms in more severely ill patients and impair the ability to culture the organism in vitro, presumptive diagnosis on the basis of clinical symptoms can be useful.[131] This is easiest for patients in endemic areas, patients infected during outbreaks, and those with classical dysentery. For example, in rural Bangladesh prospective community-based studies have shown that bloody, mucoid diarrhea accounts for two fifths of diarrhea episodes and two thirds of fatalities, about half associated with documented shigellosis.[132] The presence of many leukocytes and erythrocytes in stool adds to the suspicion of shigellosis.[133] In contrast the ability to make a correct presumptive diagnosis based on clinical features alone in the more highly endemic regions of the United States is less feasible than it was in the past when the prevalence of *Shigella* infection was as high as 33%.[134] In rare instances, *Shigella* patients develop seizures, sometimes even before the diarrhea presents, and therefore may be thought to have meningitis. Examination of the cerebrospinal fluid is usually normal, and the correct diagnosis becomes apparent when the intestinal manifestations develop, the stool is cultured, and the organism is identified.

The increasing prevalence in the United States of infection with Shiga toxin-producing *E. coli* (STEC), including serotype O157:H7 and many others, has introduced a new diagnostic dilemma. Bloody diarrhea with seizures due to the microangiopathic systemic complications of Shiga toxins produced by these organisms can be confused with

Table 7. Outcome of Patients Infected with *Shigella* Admitted to a Diarrhea Treatment Unit, Dhaka, Bangladesh, 1983–1987

Species or serotype	Total admissions	Discharged alive	Left against advice	Transferred elsewhere	Died in hospital
S. dysenteriae 1	1,251	976 (78%)	136 (11%)	40 (3%)	99 (8%)
S. dysenteriae 2–10	132	112 (85%)	5 (4%)	2 (2%)	13 (10%)
S. flexneri	2,319	1,841 (79%)	211 (9%)	39 (2%)	230 (10%)
S. boydii	303	245 (81%)	24 (8%)	3 (1%)	31 (10%)
S. sonnei	145	119 (82%)	12 (1%)	2 (1%)	12 (8%)

shigellosis (Chapter 14). At the present time, it is known that antimicrobial therapy is useful in shigellosis, and early treatment appears to reduce the frequency of HUS[135]; it is not as certain in enterohemorrhagic *E. coli* infection. Selective culture methods using sorbitol–MacConkey agar and ELISA tests for Shiga toxins in stool are useful ways to diagnose *E. coli* O157:H7 and other *E. coli*.[136] DNA-based tests are being developed, including gene probes and polymerase chain reaction methods; however, as in other areas of diagnostic microbiology, these have not yet made it to the clinical laboratories.

In developing countries, where the vast majority of *Shigella* infections occur, laboratory facilities for standard microbiological isolation of the organism, let alone immunoassay tests, are often not available, and diagnosis is dependent on clinical evaluation, aided by stool microscopy for white blood cells. The major differential diagnosis, *E. histolytica*, is a much less common cause of dysentery in children and does not cause a purulent stool because the organism destroys neutrophils. In practice, all children with clinical dysentery in endemic regions should be presumed to have *Shigella* and treated accordingly. Under optimal conditions, the stool should be examined for motile amoebic trophozoites containing ingested erythrocytes to rule out amoebiasis. In adults, the incidence of amoebic dysentery is higher than in children, and a microscopic examination of stool is important to discriminate between the two illnesses.

9. Control and Prevention

9.1. General Concepts

Even though the infective inoculum for *Shigella* infection is small and person-to-person contact spread is common, it is surprising how effective simple hygiene measures can be used in control and prevention of shigellosis.[137] Hand washing and sanitary disposal of feces constitute the keystones of personal hygiene and will minimize the spread of infection within the household. Protection of food and water for drinking and cooking from potential contamination is a critical part of this approach. Within the community, the integrity and availability of the water supply and its protection from fecal contamination is important; this is most obvious when breaks in the system permit waterborne disease. Unsanitary latrines, which allow feces to be deposited directly on the ground or in a body of water, concentrate infectious agents and facilitate transmission and are no doubt worse than no latrine at all.[138] Programs to build latrines should focus on simple sealed latrines such as the VIP (ventilated improved pit) latrine and its modification for areas with a high water table to avoid contamination of groundwater.[139] Breast-fed infants are at lesser risk of symptomatic *Shigella* infection than are bottle-fed neonates, and good nutritional status may limit the extent of acute infection and the chronicity of established illness.[75]

Travelers to endemic regions of the world are at risk of enteric infection, including shigellosis, primarily from contaminated food or water.[140] Flies may contribute to the transmission of shigellosis in areas where they are plentiful and feces are not hygienically disposed of. Simple baited fly traps can be built locally for little cost and appear to be highly effective but are not required (Table 6).[90,137]

It is wise for physicians making the diagnosis of acute shigellosis in one family member, usually a young child, to consider the whole family to be at risk. However, younger contacts of the index case are more likely to develop symptomatic secondary infection than are adults.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis and Treatment

Daily high-dose bismuth subsalicylate (BSS, PeptoBismol®) has previously been shown to be protective against bacterial causes of travelers diarrhea, including *Shigella*, for adult travelers to Mexico.[141,4] However, the protection is modest and does not warrant the large number of tablets that must be taken, the limit of 3 weeks prophylaxis because of the potential accumulation of toxic levels of bismuth, the lack of safety in children under 3 years, and the potential side-effects of "black tongue."[142]

There is widespread interest to prevent or treat enteric infections with probiotics, harmless commensal bacteria that can colonize the intestine and prevent pathogens from establishing infection or possibly favorably modify the host cell response to pathogens.[143] Experimental evidence in animal or cell culture models suggest that certain probiotics can modify the severity of *Shigella* infection. In an in vivo model of infection in rats, pretreatment with *Lactobacillus rhamnosus* and *L. acidophilus* significantly attenuated the inflammatory changes associated with *S. dysenteriae* type 1 infection.[144] Cultured intestinal epithelial cells exposed to *L. casei* followed by challenge with *S. flexneri* demonstrated a marked downregulation of inflammatory mediator gene expression, which could decrease clinical manifestations in a real infection.[145] Convincing clinical trials in humans have yet to be conducted, and whether or not probiotics can be used for prophylaxis in high-risk settings for shigellosis or would be additive therapy remains unanswered.

Recent emphasis on the role of micronutrient deficiencies, including vitamin A and zinc, on susceptibility and response to acute diarrhea has suggested the potential of

routine supplementation to prevent diarrhea and/or use of these nutrients as adjunct treatment.[146] Clinical data are limited, and often contentious, as in the case of vitamin A supplements to treat shigellosis in Bangladesh.[147,148] Zinc supplementation is reported to significantly shorten the duration of acute shigellosis, improve weight gain during recovery, and reduce the burden of diarrheal episodes for the next 6 months of follow-up.[149]

There is little information on the utility of prophylactic antimicrobials for shigellosis, and much to suggest this is inappropriate because of the rapidity with which antibiotic resistance develops. Prophylaxis with antibiotics would only make sense for short-term visitors to an endemic region, because in endemic settings, exposure to infection occurs much too frequently to make prophylaxis a viable consideration for the local population or even for resident expatriates. Because of widespread resistance to the usual drugs proposed for prophylaxis of diarrhea in travelers, the introduction of rifaximin, a non-absorbable rifamycin antibiotic, is being touted as the drug to use.[150] In a trial using experimental infection with *S. flexneri* 2a in human volunteers, rifaximin completely prevented diarrhea and dysentery (vs. 60 and 10% for the placebo control group).[151] The use of antimicrobial agents for prophylaxis could be considered in outbreaks, for example to prevent intrafamilial spread or reduce disease among contacts at risk, but the concern remains that excessive use would rapidly select for resistance. In confined outbreaks, such as newborn nurseries, standard methods of cohorting, implementation of strict sanitary measures, bacteriologic screening of medical staff, and judicious use of antimicrobials can bring an epidemic to a halt.[152]

Antimicrobial treatment of shigellosis should be regularly employed for dysentery, considered in bloody diarrhea, depending on clinical severity and the underlying health of the patient, and withheld in mild watery diarrhea. The latter recommendation is especially valid for management of otherwise healthy subjects in areas where *S. sonnei* prevails, since such infections are almost always self-limited without the use of antibiotics. Recently multidrug-resistant *S. sonnei* have emerged and are spreading globally,[100] and it is likely that resistance will continue to evolve as antibiotic use grows. It is necessary to know the prevalence of resistance and to monitor this over time in order to use antibiotics most effectively when appropriate. Quinolones are the best option for adults in most regions of the world and are increasingly seen as safe in children, despite concerns about an association with arthritis.[153] With more common use of quinolones, especially in developing countries where such drugs are readily available, there is a danger that resistance will emerge, and such strains are being detected in travelers returning to developed countries.[154] Parenteral cephalosporins have been a standby when oral drugs fail; however, the spread of extended spectrum cephalosporinases in *S. sonnei* auger poorly for the future. A large outbreak of dysentery due to resistant organisms has occurred in Taiwan.[155] Resistance to azithromycin in Bangladesh strains has been increasing, even though use of the drug is still limited due to cost.[45] Early treatment with effective antibiotics has been shown to reduce the frequency of one of the life-threatening complications of *S. dysenteriae* type 1 infection, hemolytic–uremic syndrome, associated with a decrease in the content of Shiga toxin in the stool.[135]

9.3. Immunization

There is no licensed vaccine for shigellosis at this time, but not because of a lack of effort to develop one. In fact, effective prototype vaccines have been prepared for oral use in humans, but none to date is both effective and safe.[156] Because acquired immunity is serotype specific, an ideal vaccine would have to do much better by inducing protection to multiple serotypes. Otherwise, a combination of vaccines inducing protection against single serotypes would need to be developed, which increases the cost of development and the cost of any effective product that emerges.

Although most modern approaches to vaccine development for enteric infection have concentrated on live oral attenuated vaccine strains or recombinant bacteria expressing protective antigens, there has also been a return to the testing of parenteral or oral killed vaccines or antigens. Parenteral immunization with killed organisms has never been shown to be protective in humans, although there has been success in animal models.[157] New constructs of *Shigella* LPS O-antigens conjugated to protein carriers induce IgG antibodies in both young children and adults that may be protective.[158,159]

Serum IgG antibodies reaching the lamina propria may prevent shigella invasion and growth in inflammatory cells, the release of cytokines, and the invasion of epithelial cells, thus attenuating infection at the earliest stages of pathogenesis. Time will tell whether this approach will succeed, although the presence of mild fever in 5–10% of volunteers suggests the reactivity may be a problem for regulatory approval in the United States.

Because of the role of Shiga toxin in producing the severe disease due to *S. dysenteriae* 1 and in the pathogenesis of systemic microangiopathic disease in this infection and in STEC, attempts to develop a safe toxin immunogen for active immunization or antibodies for passive immunization have been initiated.[160] Toxin is a complex protein consisting

of one biologically active A subunit and five B subunits involved in binding to host cells. Various groups are testing mutationally inactivated A subunit holotoxins, isolated recombinant B subunit, or synthetic peptides linked to protein carriers by conjugation or synthesized as recombinant fusion proteins. Promising results have been obtained in animal models; however, it will be a while before such vaccines are tested in humans. Passive immunization with anti-toxin to *E. coli* Stx-2 have been successful in preventing systemic complications in animal models.[161] These various products are being developed primarily for the prevention or treatment of STEC infections, but if effective they will surely be useful in reducing the severity and complications of *S. dysenteriae* type 1 infections.

10. Unresolved Problems

10.1. Epidemiology

Because shigellae are so host-adapted to humans and a few subhuman primates, there is an absolute need for constant passage of the organisms through these hosts. At first glance, it would seem improbable that the organism could survive this restriction when environmental sanitation and protected water supplies limit transmission by the water route. Nonetheless, we know that the organism persists under these conditions, indicating continual person-to-person or foodborne transmission. It is uncertain how in fact the organism does maintain itself, particularly during periods of low prevalence. The role and importance of asymptomatic carriers may be much greater than previously thought. The reasons for the major shifts in prevalence of *Shigella* species in different regions over time are also not known. The use of newer molecular methods to detect organisms and for typing isolates should help unravel many of the questions relating to the presence and transmission of infection in the community.

10.2. Pathogenesis

Spectacular progress has been made in defining the pathogenesis of *Shigella* infections since the application of modern molecular and cellular biology approaches. These studies have served to demonstrate how complex this process is, that multiple virulence genes are required, and that the host factors altered by the organism plays a major role in the development of clinical illness. Most progress has occurred in the mechanism of host cell invasion and in the regulatory mechanisms for inflammatory responses. We still know too little of the specific role and mechanism of toxins, including Shiga toxin and the Shigella enterotoxins Shet-1 and -2 in pathogenesis of local events in the gastrointestinal tract or in the causation of systemic pathology. Elucidation of the specific mechanisms involved is essential for the development of therapeutic and prophylactic measures.

Rational pharmacological manipulation of the secretory or inflammatory process in the intestinal tract is equally dependent on specific knowledge of the mechanisms involved. These take on particular significance when the problems of epidemiology and antimicrobial drug resistance are considered.

10.3. Antimicrobial Resistance

Transferable multiple antimicrobial drug resistance mediated by plasmid DNA was first discovered in *Shigella*, ushering in a dramatic rise in the prevalence of highly drug-resistant shigellae in Japan and subsequently elsewhere as antibiotic pressures led to selection of the plasmid-bearing organisms. Resistance clearly restricts the efficacy of antimicrobial therapy of acute shigellosis. The principal strategy in dealing with acquired drug resistance has been to develop new or modify old drugs to preserve antimicrobial activity. This merely buys time; the ultimate solution is to learn how to control transferable drug resistance in nature. If it were possible to remove these plasmids in vivo it would restore susceptibility to the drugs already available for use and known to be effective, to be inexpensive, and well tolerated. If we knew how to accomplish this it could have the added advantage of curing plasmids bearing essential virulence traits, rendering the survivors nonpathogenic. The theoretical barriers to this are enormous and are further complicated by the tissue- and cell-invasive characteristics of *Shigella*, which insure a protected reservoir of fully virulent and drug-resistant organisms unless the strategy is effective beyond the intestinal lumen. Even so, the ability to cure undesirable plasmids in nature could have important effects on the prevalence of fully virulent organisms excreted into the environment.

Other ways to approach these issues at a more practical level involve control and restriction in the use of antimicrobial agents. In the United States, where such drugs are dispensed only by prescription, physician and patient education could have a major impact; however, success in such programs has been limited. Even if this were accomplished the use of similar or identical drugs in agriculture to promote the growth of meat animals, which selects for resistance, could overcome the benefits of reducing antibiotic use in humans. In developing countries, despite the efforts toward essential national drug programs, there is no control over dispensing

antimicrobials, which are freely available on the market and are used indiscriminately. The need for legislation and effective agencies to monitor and control drug use comes into conflict with the enormous potential economic gains for both local and multinational drug manufacturers as well as local drug merchants, including pharmacists and untrained dispensers, and the problem of insuring that patients have access to the drugs they may need when access to medical care is so limited.

10.4. Clinical Complications

The pathogenesis of most of the clinical complications that occur in shigellosis is not well understood. Since certain of these complications, including microangiopathic hemolytic anemia, hyponatremia, and thrombocytopenia, occur almost exclusively in association with *S. dysenteriae* 1 infection, speculation has centered on the role of Shiga toxin produced by this organism. The discovery that Shiga toxin-producing *E. coli* cause similar systemic events in children in developed nations and the occurrence of outbreaks involving large numbers of individuals in the United States have stirred research interest and have led to increased support for research. Much remains to be done.

Toxic megacolon is another complication associated with significant mortality. It is logical to assume that the extent of the inflammatory changes is the major determinant of toxic dilatation, but little is known in fact. Therapy requires appropriate antimicrobials and general support with fluids, reserving surgery for those who do not respond or whose colon perforates. New data on the cytokine response in shigellosis suggest that these inflammatory mediators play a major role in inflammatory complications. Further studies on their role in pathogenesis are warranted, and the potential of new anticytokine strategies of therapy in this and other complications is an exciting new area for study.

In the case of Reiter's arthritis, there is a clear genetic predilection for HLA-B27-positive subjects. The mechanisms underlying this particular host response to the infection need to be understood. Therapy or, even better, prevention could then be considered. This is clearly important because of the chronic destructive joint disease initiated by the organisms.

Shigella infection is associated with the most severe nutritional consequences of all the diarrheal diseases. In developing countries, this malnutrition is strongly associated with mortality, and there is growing evidence that the mortality rate in patients in the months after discharge from the hospital after shigellosis is far greater than in those discharged after watery diarrhea due to *E. coli*, cholera, or rotavirus. Nutritional effects of the infection may account for this in large part. The relative importance and persistence of mucosal inflammation, systemic catabolic responses, and protein-losing enteropathy are uncertain, and there are no pathogenesis-based innovative approaches to prevention and treatment.

10.5. Vaccines

Because of unresolved questions of pathogenesis and the failure to develop acceptable vaccines, the question of prophylaxis is open to investigation. It is apparent that our current understanding of host defenses and the nature of the protective immune response in shigellosis is wanting. When success does not come easily with conventional approaches, it is time to stop and reason. In the present context, this means more studies to define the protection-eliciting antigens of the organisms and to find a way to present these to the host without toxicity or unacceptable side-effects to achieve the protection desired.

CHAPTER 34

Evans' Infections of Humans: Staphylococcal Infections

Zeina A. Kanafani and Vance G. Fowler, Jr.

1. Introduction

Despite major advances in the medical arena, staphylococci remain important agents of infectious diseases in the human host. Although initially disregarded as contaminants in cultures, coagulase-negative staphylococci have recently gained great clinical significance and are now recognized as potentially virulent pathogens associated with significant morbidity and mortality.[1] The emergence of antibiotic resistance has also brought renewed attention to staphylococci. Methicillin-resistant *Staphylococcus aureus* (MRSA) is now considered a major public health problem both in the hospital and in community settings.[2–4]

2. Historical Background

Approximately 100 years ago, von Recklinghausen used the term "micrococci" to describe gram-positive cocci observed in diseased tissue and in pus from human abscesses. In 1881, Sir Alexander Ogston published extensive observations showing that a cluster-forming coccus was the cause of certain pyogenic abscesses in humans.[5] He subsequently named the organism *Staphylococcus*, derived from the Greek nouns *staphyle* (grapes) and *coccus* (grain or berry). He distinguished staphylococci from streptococci and produced disease in mice by subcutaneous inoculation of staphylococci recovered from pus. In 1884, Rosenbach was able to isolate staphylococci in pure culture and observed that staphylococcal isolates formed colonies of two different colors.[6] He named the orange colonies *S. aureus* and the white colonies *S. albus*. After making the distinction between *S. aureus* and the other staphylococci, Rosenbach showed that *S. aureus* was responsible for wound infections, while the other staphylococci were normally found on the skin as colonizers.

In the following years, staphylococci were recognized as causes of important and sometimes lethal infections, including surgical wound infections and pneumonia.[7,8] The discovery of the antibacterial activity of the mold *Penicillium* in 1928 by Fleming[9] and the subsequent production of penicillin gave scientists hope that all infectious diseases will be promptly eradicated.[10] For a period of time, staphylococcal infections became less important causes of nosocomial infections than gram-negative bacilli. However, the rapid emergence of resistant isolates of *S. aureus* just 1 year after penicillin was marketed was capable to reverse the tide and allow staphylococci to ascend to the forefront of infectious diseases.

3. Methodology

3.1. Sources of Mortality Data

Most staphylococcal disease is localized to the skin and is not fatal. Once infection becomes generalized and bacteremia occurs, mortality is great despite appropriate antibiotic therapy. Data on mortality from bacteremic staphy-

lococcal infections have come from national surveillance[11] and from hospital studies[12–14] with comparable findings.

3.2. Sources of Morbidity Data

The incidence of all staphylococcal disease in the community can be assessed only indirectly, since minor disease may never come to medical attention.[15] The incidence of more serious disease, including bacteremia, can be estimated.[16,17] Staphylococcal disease is not part of the national reportable disease surveillance system. Hospital surveillance has provided reliable data on hospital-acquired staphylococcal disease[12,18,19] and on methicillin-resistant *S. aureus* disease in long-term care facilities.[20,21]

3.3. Surveys

Household- and population-based surveys have provided a wealth of data on community-acquired morbidity from staphylococci.[22,23] Hospital-based surveillance for staphylococcal disease, community and nosocomially acquired, allows for ongoing assessment of serious staphylococcal disease.[12,18,19] Hospital surveillance begins from laboratory cultures reporting staphylococci; hence, it may underestimate the incidence of disease when cultures are not taken. Typing of staphylococci in the laboratory permits identification of strains responsible for outbreaks or epidemics.[24]

3.4. Laboratory Diagnosis

Staphylococci can be recognized quickly and reliably on Gram stains of exudates from most clinical specimens. Their lack of fastidiousness permits their growth on ordinary laboratory media.[25] Selective media such as that containing mannitol and 6.5% NaCl have expedited recognition of staphylococci grown from swabs of throat, nose, or other contaminated areas and have permitted rapid evaluation of staphylococcal carriage by individuals. Once grown, *S. aureus* is identified by a positive coagulase test.

There are over 30 species of coagulase-negative staphylococci. Although many clinical laboratories do not routinely speciate coagulase-negative isolates, they can be distinguished by a variety of biochemical reactions. *S. epidermidis* accounts for the majority of clinical isolates, with *S. haemolyticus* and *S. hominis* next in frequency.[26] Antibiotic sensitivity of staphylococci as measured by a Kirby–Bauer disk technique is widely used,[27] although in selected instances, tube-dilution techniques permitting the determination of minimal inhibitory and bactericidal concentrations are more valuable.[28] Phage typing of staphylococci has permitted identification of specific strains and has allowed for the recognition of prevalent and epidemic strains. Molecular methods of typing, such as plasmid analysis or restriction endonuclease analysis of whole-cell DNA, are highly reliable in differentiating staphylococcal strains[29,30]; they are more widely available than phage typing. Strain identification by antimicrobial susceptibility is unreliable.

The serological diagnosis of *S. aureus* bacteremia has been evaluated.[31] Antibodies to a variety of staphylococcal antigens have been tested including peptidoglycan, teichoic acid, *S. aureus* ultrasonicate, whole *S. aureus* cells, alpha-toxin, lipase, and capsular polysaccharide. Whole-cell ELISA has been shown to be the most sensitive assay although all tests lacked specificity. Studies suggest that the presence of antibodies to *S. aureus* teichoic acid might indicate a chronic deep-seated infection, including endocarditis, chronic osteomyelitis, and septic arthritis, whereas patients with uncomplicated bacteremia, acute osteomyelitis, cellulitis, and meningitis frequently have negative titers.[32] However, these tests have not come into clinical use. Antibodies against an exocellular glycolipid antigen in coagulase-negative staphylococci have also been used to distinguish between staphylococcal infection around prostheses and aseptic loosening.[33]

4. Biological Characteristics of the Organism

Staphylococci are nonmotile, gram-positive cocci that may occur singly, in pairs, short chains, or clusters. The characteristic appearance is that of a "bunch of grapes." They are facultative anaerobes but grow better under aerobic than under anaerobic conditions. Staphylococci grow readily on blood and chocolate agar. Colonies of *S. aureus* measure 1–3 mm and typically produce a yellow to golden pigment due to the presence of carotenoids. Most other species are nonpigmented. Most strains of *S. aureus* produce hemolysis within 24 to 36 hours on horse, sheep, or human blood-agar plates. They usually produce catalase. Traditionally, they have been divided into coagulase-positive and coagulase-negative staphylococci. The following enzymes and toxins that are produced by staphylococci are often considered of importance in human virulence:

1. *S. aureus* produces two antigenically distinct enzymes: bound and free coagulase, both capable of coagulating human serum. Their role in infection is unclear, but the presence of this enzyme serves to distinguish the more virulent species, *S. aureus*, from other species.
2. Alpha-toxin causes direct damage to a variety of mammalian cell membranes including erythrocytes, leukocytes, and fibroblasts.
3. Leukocidin is an extracellular protein that acts on human polymorphonuclear leukocytes in vitro. It causes death of white blood cells, but its role in infection is unclear.

4. Enterotoxin: Most *S. aureus* strains produce one or more enterotoxins that are responsible for the syndrome of staphylococcal food poisoning. A smaller percentage of *S. epidermidis* strains produce enterotoxin; these have rarely been implicated in food poisoning.[34]
5. Exfoliative toxin: Staphylococci of phage group II produce a toxin responsible for the dermatologic manifestations of infection that go under the general heading of "scalded-skin syndrome."
6. Toxic shock syndrome toxins: The syndrome is mostly caused by toxic shock syndrome toxin-1 (TSST-1). However, other exotoxins and enterotoxins can also be involved.[35,36] While rare, toxic shock syndrome has also been reported to be caused by TSST-1-producing coagulase-negative staphylococci.[37]
7. Enterotoxins and TSST-1 bind to class II major histocompatibility antigens and to receptors on T lymphocytes. These toxins stimulate the release of interleukin-2 and tumor necrosis factor; uncontrolled release of these lymphokines may play a pathogenic role in the clinical syndromes caused by these toxins.[38]

S. aureus specifically binds a variety of human proteins and glycopeptides, including fibronectin and fibrinogen. This binding may be an important factor in the maintenance of the carrier state and the initiation of infection. Clinical isolates of coagulase-negative staphylococcus, from patients with clinical infections, appear to produce an extracellular polysaccharide ("slime factor") that enhances adherence to plastic or metal surfaces.[39] This slime layer also inhibits diffusion of antibiotics, impairing their ability to reach organisms.[40] In addition, the slime material interferes with the lymphoproliferative response to mitogens[41] and also alters polymorphonuclear functions such as decreasing responsiveness to chemotactic stimuli and inhibiting phagocytosis of coagulase-negative staphylococci.[42] Coagulase-negative staphylococci have the ability to erode into polyethylene catheters and prosthetic devices, which may also allow increased adherence of the organisms.[39,43] Catheter-adherent coagulase-negative staphylococci appear to possess survival mechanisms under adverse conditions (absence of conventional nutrients) that may be important in the genesis of occult foreign-body-associated infection.[44]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Staphylococci have long been recognized as a hospital problem, and the policy of routine ongoing surveillance for hospital-acquired staphylococcal disease is well justified.[45–47] *S. aureus* is the leading cause of postoperative wound infection and the second-most frequent cause of nosocomial pneumonia.[48] Coagulase-negative staphylococci are now the leading cause of primary nosocomial bacteremia, accounting for 29% of cases.[48] During the period 1980–1989, the rate of bloodstream infections due to coagulase-negative staphylococci in large teaching hospitals rose from 0.2/1,000 discharges to 1.8/1,000.[49] The widespread use of invasive devices, such as pacemakers, central venous catheters, and hemodialysis catheters has contributed significantly to the temporal increase in healthcare associated staphylococcal infections.[48]

Serious staphylococcal disease may be acquired outside the hospital. The prevalence of such infections has recently increased significantly. In particular, community-associated MRSA (CA-MRSA) has become a public health concern, with the USA300 strain being predominant in the United States (1, 2). Despite few data on incidence rates, the burden of CA-MRSA infections is significant. For example, a Texas-based study in children noted a 14-fold increase in the rate of CA-MRSA infections (3). Similarly among adults, the incidence of CA-MRSA varied from 15 to up to 74% (4).

5.2. Nasal Carriage

S. aureus may be carried by normal people at various body sites without causing disease. The nose is the principal site of carriage; cross-sectional studies reveal rates of 30–50% in persons outside hospitals and higher rates in hospital nursing personnel.[54,55] More recent studies have demonstrated an increase in the rate of nasal colonization with methicillin-resistant *S. aureus* (MRSA) both in the community and in hospital settings.[56,57] Longitudinal studies have shown persons to be persistent carriers (20%), intermittent carriers (60%), or persistent noncarriers (20%).[58] Skin carriage has been demonstrated in 85% of persons with atopic dermatitis, suggesting a strong predisposition to carriage.[59] *S. aureus* carriage in infants is determined by a combination of host, environmental, and bacterial factors. After the eighth week of life, the carriage rate declines as infants develop an immune response to *S. aureus* and spontaneously clear the colonization.[60]

Carriage may precede or indeed lead to disease in susceptible individuals.[61] Patients on continuous ambulatory peritoneal dialysis who are carriers had a significantly higher infection rate than noncarriers.[62] Other populations at risk include surgical patients,[63] hemodialysis patients,[64] HIV-infected patients,[65] and those with intravascular devices.[66]

5.3. Epidemic Behavior and Contagiousness

S. aureus can be highly contagious through direct contact with the large numbers of organisms present in lesions. The condition of the host clearly influences the frequency and severity of disease produced by staphylococci. Within a

household, any strain of *S. aureus* can colonize family members and cause disease sporadically or it may cause continuous and repeated episodes of infection.[2]

Over the years, epidemics of *S. aureus* infections have been recognized throughout the world.[67,68] Outbreaks have been reported in a variety of settings including the community[69] as well as hospitals,[70] long-term care facilities,[71] and outpatient clinics.[72] A wide variety of hosts can also be affected including immunocompetent individuals[73] and patients with chronic diseases and altered defenses.[74] Nosocomial outbreaks have frequently been ascribed to colonization of the nares and hands of health care workers.[75,76] Finland[77] and others[68] have suggested that the epidemic character of *S. aureus* may relate, in part, to genetic properties of the organism. The changing susceptibility and resistance of *S. aureus* to bacteriophages or properties of the phages themselves may create within *S. aureus* the changes required for enhanced virulence. The changing antigenic character and epidemic properties of *S. aureus* may thus be analogous to the changing influenza A viruses and their epidemiological virulence.

The epidemic potential of *S. epidermidis* has also been demonstrated. Several outbreaks have been described, particularly in surgical patients[78,79] and those with indwelling catheters.[80]

5.4. Geographic Distribution

Infections with *S. aureus* are worldwide in distribution.[77] While the penicillin-resistant phage type 80/81 caused infections worldwide, the more recent methicillin-resistant strains have been of several phage types or were nontypeable[67] and are now widespread in Europe and [81,82] the United States[83,84] and occur worldwide.[85]

Penicillin-resistant forms of *S. aureus* do occur in nature,[86] and penicillinase-producing strains from the pre-antibiotic era have been reported.[87] In contrast, there is no clear documentation of resistance to other anti-staphylococcal drugs prior to their clinical use.[88]

5.5. Age

Children have higher rates of carriage and persist as carriers more commonly than do adults.[89] Mortality from serious staphylococcal infection is age related, with higher rates in the very young and older age groups.[90,91]

5.6. Sex

Male gender was found to be a risk factor for *S. aureus* nasal carriage in preoperative patients,[92] although other studies have not shown the same association.[93] On the other hand, infection[94] and mortality[95,96] rates were similar for both males and females in several studies.

5.7. Race

No racial predisposition for *S. aureus* has been noted.

5.8. Occupation

Health care workers who come in contact with patients colonized or infected with *S. aureus* have higher rates of nasal carriage than persons without such contact,[97,98] and they may develop clinical disease from such carriage.[99]

5.9. Socioeconomic Factors

There is little to suggest that socioeconomic factors influence the occurrence of staphylococcal disease. Overcrowding, poor skin hygiene, or minor skin trauma may play a role in predisposing to *S. aureus* bullous impetigo, but the association is greater for streptococcal pyoderma.[100]

5.10. Other Factors

A variety of underlying conditions predispose to *S. aureus* infection.[72,94,101–103] Extremes of age,[94,104] recent influenza A infection,[105] exfoliative skin disorders,[106] autoimmune disorders,[107] diabetes,[94] chronic renal failure,[108] liver disease,[101] and intravenous drug abuse[109] are associated with an increased risk of infection. In addition to surgery,[102] vascular catheters,[110] and dialysis,[111] medical interventions that predispose to infection with *S. aureus* include insertion of prosthetic devices[112] and administration of corticosteroids and other immunosuppressive agents.[113] The use of antibiotics has clearly influenced the epidemiology of *S. aureus* infections.

Coagulase-negative staphylococci are part of the normal skin flora and are uncommon pathogens except in the presence of foreign bodies (prosthetic valves, CSF shunts, prosthetic joints, and intravenous catheters). Immunocompromised hosts and neutropenic patients appear to have an increased susceptibility to severe infections, such as bacteremia, with these organisms. It is sometimes hard to separate the roles of foreign bodies versus immunocompromised status. For example, intravascular catheters are an important portal of entry in immunocompromised hosts; however, overgrowth at respiratory and gastrointestinal sites may also serve as sites of entry in such hosts even without a foreign body.

6. Mechanisms and Routes of Transmission

Contact transmission has also been observed with CA-MRSA among athletes (1), prison inmates (2), and day care attendants (3). Transmission of *S. aureus* outside of the hospital occurs through person-to-person spread within families or intimate contacts.[2,23] Studies within the hospital show that the nasal carrier is predisposed to postoperative infection with the same strain.[117] Also within hospitals, other vectors for infection exist with infected patients,[70] health care personnel[75,76] who are infected or are carriers, and fomite contamination.[118,119] Airborne spread of *S. aureus* can be demonstrated[120,121]; however, it has been difficult to correlate counts of staphylococci in air with infection rates. Patients on broad-spectrum antibiotics have been shown to have increased shedding of resistant staphylococci.[122] The infected lesion sheds heavy concentrations of organisms and is potentially the greatest hazard for spreading infection.[123]

Humans are the natural reservoir for *S. epidermidis*; these bacteria are part of the normal skin flora and are the most common staphylococcal species isolated from cutaneous sites. The organism is easily shed from skin and can contaminate inanimate environmental surfaces, other people, and the air. The resistance of the organism to drying and temperature changes produces a long viability.[124] *S. epidermidis* infections result from contamination of a site (usually surgical) by organisms from the patient's skin or nasopharynx or from exogenous sources. Outbreaks of *S. epidermidis* in post-surgical patients have been widely reported.[78,79,83]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Foreign bodies enhance the likelihood that staphylococcal infection will develop by reducing the number of organisms needed to initiate infection. Healthy persons require more than 10^6 virulent staphylococci to cause a minor infection, whereas 10^2 organisms can result in an infection when a foreign body is present.[125] Sutures,[102] intravascular catheters,[110] prosthetic joint devices,[112] artificial heart valves,[126] and tracheostomy[127] and endotracheal[128] tubes are examples of commonly used foreign bodies that may become infected. Fibrin may be responsible for staphylococcal adherence to intravascular catheters.[129] Bacteremia may arise from the local site and can lead to *S. aureus* infection and abscess formation in any organ of the body. Sequelae include such entities as meningitis,[130] osteomyelitis,[131] and endocarditis.[132] Damaged tissue, e.g., the skin in burns and the airways in influenza, are predisposed to colonization and then proliferation of *S. aureus*. A consequence in burn patients is septicemia[133] and in influenza patients, *S. aureus* pneumonia.[105]

S. aureus is a complex organism with a variety of bacterial products with the potential for promoting disease.[134] Potential virulence factors include surface proteins that promote adherence to damaged tissue,[135] bind proteins in blood to help evade antibody-mediated immune responses[135] and promote iron uptake.[136] The organism also expresses a number of proteins that can cause tissue damage by enzymatic action, and superantigen toxins which are potent cytokine inducers.[137] Extracellular products associated with disease include enterotoxins, which produce food poisoning, and exfoliatin which causes scalded-skin syndrome. In toxic shock syndrome, an extracellular toxin (now known as TSST-1) of *S. aureus* related to phage group I is believed to mediate the multiple observed clinical manifestations.[138] Genes that encode virulence factors can be located on mobile genetic elements called pathogenicity islands (e.g., toxic shock syndrome toxin-1 and some enterotoxins),[139] on lysogenic bacteriophages (e.g., Panton–Valentine leucocidin [PVL]),[139,140] or can be integrated into the bacterial chromosome (factors associated with suppressing innate immunity such as the chemotaxis inhibitory protein and staphylokinase).[141]

As with *S. aureus*, the presence of foreign bodies markedly enhances the likelihood of infection with coagulase-negative staphylococci. Indeed, *S. epidermidis* is generally not a pathogen except in the presence of a foreign body, in an immunocompromised host, or in patients with neutropenia. As described earlier, the ability of a coagulase-negative strain of staphylococcus to secrete a slime layer appears to offer it advantages in terms of colonization, persistence, and infection. In one study, 81% of 59 infectious episodes in patients with a prosthetic device were due to a slime-positive coagulase-negative staphylococcus. Slime-positive organisms producing infection were significantly harder to eradicate than slime-negative organisms.[142]

7.2. Immunity

Humans enjoy a high degree of natural resistance to *S. aureus*. The exact nature of this natural immunity is not clear and may be nonspecific.[143] While humans show little resistance to superficial colonization with *S. aureus*, there is great resistance to progressive forms of disease.[143] Spread of staphylococcal infection is limited by reticuloendothelial system clearance and polymorphonuclear leukocyte chemotaxis and ingestion of bacteria.[144,145] This requires blocking the coordinated action of the various cell wall-associated and secreted bacterial proteins.[146] Although IgG

antibodies to specific components of *S. aureus* have been demonstrated,[147] and components of the classic and alternative complement systems have been shown to be necessary at times for efficient phagocytosis of staphylococci,[148] the overall significance of opsonization in immunity to *S. aureus* is unclear.[144,149] IgE antibodies to *S. aureus*, demonstrated in patients with recurrent "cold" abscesses, may represent an abnormal immunologic response to *S. aureus* and more specifically to the cell walls of the bacteria.[150,151]

The role of cell-mediated immunity to *S. aureus* remains to be defined.[149,152] Filtrates from strains of *S. aureus* contain mitogens for human lymphocytes.[153] Delayed hypersensitivity reactions to *S. aureus* have been demonstrated in animals, but are not associated with increased resistance.[152] Indeed, repeated skin infections in a rabbit model produced increased susceptibility to *S. aureus* skin and joint infections, suggesting that delayed hypersensitivity may have a pathogenetic role in staphylococcal disease.[154]

The capsular polysaccharides of *S. aureus* inhibit opsonization and phagocytic killing by polymorphonuclear neutrophils, thereby facilitating the development of invasive staphylococcal infection.[155] Antibodies to the capsular polysaccharides of *S. aureus* types 5 and 8 induce type-specific killing by human neutrophils in vitro and confer protection in animals.[156] When conjugated with carrier proteins, the immunogenicity of the capsular polysaccharides is enhanced by conjugation with carrier proteins.[157–159] A monovalent vaccine containing *S. aureus* type 5 or type 8 capsular polysaccharide bound to recombinant exoprotein A, a nontoxic variant of *Pseudomonas aeruginosa* exotoxin A expressed in *Escherichia coli*, has been developed and was found to be immunogenic and well tolerated.[160]

8. Patterns of Host Response

Staphylococci may infect and cause disease in virtually every organ system of the body. The organism is highly virulent for humans and, with the exception of the anterior nares, the pharynx, and skin, rarely lives in symbiosis with the host. Within the nose and pharynx and on the skin, staphylococci may exist as part of the "carrier" state; their importance in such locations is the capacity to be spread to other sites within the host or to other susceptible individuals. The manifestations of staphylococci infection vary depending on the site involved and will be described separately. Table 1 summarizes some of the features of selected forms of *S. aureus* infections.

Table 1. Clinical Forms of Staphylococcal Infections

Category	Age most often afflicted	Special risk factors
Boils, furuncles, carbuncles	All ages	Diabetes mellitus
Wound infections	All ages	Diabetes mellitus, steroid therapy, obesity, malnutrition, prolonged surgery, foreign body (e.g., prosthesis)
Breast infections	Newborn, women in puerperium	None
Pneumonia	All ages	Drug addiction, influenza outbreaks
Endocarditis	All ages	Heroin addiction, prosthetic heart valve
Skin infections		
Bullous impetigo	Childhood	None
Scalded-skin syndrome	Childhood	Compromised host
Thrombophlebitis	All ages	Intravenous catheters
Bacteremia	All ages	Diabetes mellitus, leukemia, lymphoma
Osteomyelitis	Children	None
Septic arthritis	All ages	None
Food poisoning	All ages	None
Parotitis	Elderly	Dehydration
Toxic shock syndrome	Younger women	Use of vaginal tampons during menses, after childbirth, surgical wounds, influenza
Peritonitis	All ages	Continuous peritoneal dialysis
Urinary tract infection	Young women	None or urinary tract abnormality
Cerebrospinal fluid shunt infection	All ages	Presence of shunt
Pyomyositis	Young men and boys	Tropical climate, HIV
Meningitis	Newborn infants, all ages	Prematurity, endocarditis, CNS disorders

8.1. Clinical Features

8.1.1. Boils, Furuncles, and Carbuncles. A boil or furuncle is an acute abscess of the skin and subcutaneous tissues. Such lesions occur most commonly on the face, neck, buttocks, thighs, perineum, or axillae. Exquisite tenderness is the hallmark of these lesions, which swell with pus and eventually drain spontaneously. Carbuncles are collections of interconnected furuncles that are less likely to drain externally. Carbuncles become larger, are more painful, and are associated with systemic signs and bacteremia; they appear more commonly in association with diabetes.

8.1.2. Wound Infections. *S. aureus* accounts for 17% and coagulase-negative staphylococci account for 12% of surgical wound infections.[161] Factors that have been associated with an increased incidence of wound infection are age, diabetes, steroid administration, obesity, malnutrition, increased duration of time in the operating room, and presence of other infected sites. Wound infections are usually associated with frank purulent drainage, breakdown of the wound, fever, and lack of well-being of the patient.

8.1.3. Breast Infections. Mastitis due to staphylococci generally occurs in newborns and in women (frequently in the puerperium). In neonates, the breast shows marked redness with induration resembling a furuncle. In adults, infection can be superficial, presenting only with pain and a lump; but more extensive involvement may occur with marked tenderness, fever, and leukocytosis.

8.1.4. Pneumonia. Staphylococcal pneumonia may present in one of three ways: lobar pneumonia,[56] diffuse interstitial pneumonia,[154] and localized areas of pneumonia secondary to septic emboli with infarction. In lobar pneumonia, the patients are usually acutely ill with high fever, tachypnea, and cough productive of yellow, bloody sputum. On smear of the sputum, large numbers of neutrophils and staphylococci are seen. Empyema is a frequent occurrence and in infants the development of pneumatoceles is a hallmark of staphylococcal pneumonia. Diffuse interstitial pneumonia usually occurs after or coincident with influenza. The most prominent clinical feature is tachypnea and cyanosis with refractory hypoxia. Localized areas of pneumonia secondary to septic emboli can occur with bacteremia alone or in the presence of endocarditis, particularly involving the tricuspid valve. Pleuritic chest pain, dyspnea, fever, and chills are prominent, whereas cough and purulent sputum are less likely. Roentgenographic examination frequently reveals multiple small densities at the periphery of the lung that frequently increase in size and cavitate.

8.1.5. Endocarditis. Endocarditis complicates the course of *S. aureus* bacteremia in up to 32% of cases, often with devastating sequelae.[162] *S. aureus* was the most common cause of native valve endocarditis in a large cohort of patients.[163] Endocarditis caused by *S. aureus* usually presents as an acute fulminant illness with high fever and metastatic abscesses and has the potential for lethal damage to heart valves. Staphylococcal endocarditis should be suspected in any patient with staphylococcal bacteremia and particularly in heroin addicts. Many of the classic features of endocarditis may be absent and staphylococcal disease frequently involves normal heart valves.[163] Although relatively rare, prosthetic valve endocarditis due to *S. aureus* is associated with high complication and mortality rates.[164]

Only 5% of all cases of infective endocarditis on native cardiac valves are caused by coagulase-negative staphylococci.[165] The disease is subacute and resembles that caused by viridans streptococci. On the other hand, coagulase-negative staphylococci are the most common cause of prosthetic valve endocarditis, accounting for approximately one-third of cases within the first year and only about 10% of later cases.[166] The infections are usually severe with evidence of prosthetic valve destruction and dysfunction in up to 70% of cases.[167] It is presumed that cases caused by coagulase-negative staphylococci occurring in the year following surgery are probably the result of inoculation of organisms at the time of surgery. Diagnosis of coagulase-negative prosthetic valve endocarditis requires a high level of suspicion and the findings of fever and blood cultures positive for these organisms.

More recently, health care-associated endocarditis has become increasingly common among patients with native valve endocarditis due to both *S. aureus* as well as coagulase-negative staphylococci. This subset of endocarditis is characterized by the absence of classical stigmata of endocarditis, predominance of mitral valve involvement, and high mortality rate.[162,168]

8.1.6. Skin Infections. Staphylococci of phage group II have been associated with several manifestations of infection in the skin.[169] These include bullous impetigo, a nonstreptococcal scarlatiniform rash, and toxic epidermal necrolysis (the scalded-skin syndrome). Infected individuals show an abrupt onset with diffuse erythema over most of the body. The skin is exquisitely sensitive to touch and within 1–2 days begins to peel off after light stroking (Nikolsky's sign). Large bullae filled with clear sterile fluid appear in the epidermis, which separates in sheets. Secondary desquamation continues 7–10 days after the onset of redness; recovery is complete.

8.1.7. Intravenous Catheter-Related Infections. Staphylococci are the most frequent cause of infections related to intravenous catheterization. Coagulase-negative staphylococci are most frequently isolated followed by *S.*

aureus.[170] The site of catheter insertion shows signs of local inflammation in only a minority of cases. Patients may present with fever and other systemic signs of sepsis without any obvious source of infection. Blood cultures are usually positive and culture of the intravascular portion of the catheter also yields the infecting organism. Risk factors include the long periods of time that intravenous lines now stay in place; the pressure of multiple antibiotic usages in sick patients, enhancing the likelihood of colonization with multiply-resistant coagulase-negative staphylococci; the ability of the organism to produce a slime layer; the presence of neutropenia; and the administration of other immunosuppressive drugs.

8.1.8. Bacteremia. Staphylococcal bacteremia may arise from any site where staphylococci produce infection. Forty percent of bacteremic patients have no apparent primary site of infection.[171] Bacteremia due to *S. aureus* is now classified into three categories: hospital acquired, community acquired and health care associated.[172] The incidence rates for all of the above categories have significantly increased over the last decade.[173] Hospital procedures such as surgery with subsequent wound infection or parenteral infusion via intravenous catheters are a frequent source. Patients who develop staphylococcal bacteremia frequently have underlying diseases such as diabetes, chronic renal failure, malignancy, or substance abuse.[171] The clinical picture of staphylococcal bacteremia is generally a fulminant illness with metastatic infections occurring in about a third of patients. Shock, disseminated intravascular coagulation, and respiratory failure may occur. There has also seen a significant rise in rates of MRSA recently. Approximately 30% of *S. aureus* bacteremia isolates in the United States are now methicillin resistant.[174] Widespread antibiotic use and poor adherence to infection control precautions have both contributed to the rise in MRSA infection rates.[175]

Coagulase-negative staphylococci are now the most frequent cause of hospital-acquired bacteremia.[161] The recent increase in incidence is related to the increase in the number of immunocompromised patients and an increase in the use of centrally placed intravenous catheters. Neutropenic patients are at particular risk, and the mortality in these patients is as high as 34%.[176,177]

8.1.9. Osteomyelitis. *S. aureus* is the most common cause of acute osteomyelitis.[178] It occurs most frequently in children under 12 years of age but also may be seen in adults. The clinical picture begins abruptly with fever, chills, and pain at the site of involvement. The skin overlying the bone is often warm, red, and swollen. Cultures of bone or pus will generally reveal staphylococci, and bacteremia is present in about one half of the patients. Long bones are most commonly affected in children, while vertebrae are a more common site in adults. The clinical picture of vertebral osteomyelitis may be only that of malaise and vague back pain, and an elevated erythrocyte sedimentation rate may be the only laboratory abnormality. With progression, painful muscle spasms, limitation of motion of the spine, and low-grade fever will usually develop. Osteomyelitis can occur following traumatic injury, bone and joint surgery, or as a complication of staphylococcal bacteremia. Chronic staphylococcal osteomyelitis may occur if therapy of the acute disease is delayed or even in some instances following proper treatment. A classical example is a diabetic foot ulcer infection with chronic osteomyelitis. The characteristic clinical course is an indolent one in which sinuses drain purulent material for many years.

8.1.10. Septic Arthritis. Septic arthritis in all age groups is most frequently caused by *S. aureus*.[179] The typical presentation occurs with fever, pain, and chills, and the diagnosis rests on aspiration, Gram stain, and culture of the joint fluid. Staphylococci are the most frequent cause of infected joint prostheses; *S. aureus* and coagulase-negative staphylococci are isolated with approximately equal frequency.[180] It is presumed that infections with coagulase-negative staphylococci are a result of operative contamination; however, there may be a prolonged latent period before clinical infection occurs and it is not possible to exclude hematogenous dissemination as a mechanism. The symptoms of infection may be mild, consisting only of pain in the area of the prosthesis and fever. The diagnosis must be made by culture of the joint space. Although such infections are not common, they are devastating complications because removal of the prosthesis is usually required.

8.1.11. Food Poisoning. Staphylococcal food poisoning is produced by the ingestion of food containing enterotoxin produced by *S. aureus*. The usual interval between ingestion of food containing the toxin and the onset of symptoms is relatively short, ranging from 30 min to 7 hr. Onset is usually abrupt, with severe nausea and cramps followed by vomiting, diarrhea, and prostration. Fever is usually absent and the duration of illness is generally less than 24 hr. The short incubation period, brief duration of illness, and absence of fever help distinguish staphylococcal food poisoning from other forms of food poisoning.

8.1.12. Parotitis. *S. aureus* has been recognized as one of the most common causes of acute suppurative parotitis.[179] The disease typically occurs in elderly postoperative patients who are dehydrated or intubated.[181,182] Other predisposing factors include recent intensive teeth cleaning, use of anticholinergic drugs, and salivary calculi with obstruction. Clinically, the parotid gland is erythematous, swollen, and very tender. High fevers, chills, and elevated white cell counts are generally present. Suppura-

tive parotitis also has been reported in neonates[183] and children,[184] with *S. aureus* isolated from parotid pus.

8.1.13. Toxic Shock Syndrome. This entity has been described predominately in young women who are actively menstruating, but it can also appear following all types of surgery, after childbirth, with wounds, in children, or after influenza. The individuals develop fever, an erythematous macular rash that subsequently desquamates, falling blood pressure, and then multisystem involvement. The latter has included gastrointestinal, renal, hepatic, hematologic, central nervous, and cardiopulmonary systems. *S. aureus* has been found in the vaginal cultures of nearly all menstrual cases and has been recovered from wounds in other cases. A significantly higher proportion of menstruating women with this syndrome used vaginal tampons when compared with controls.[35,36] Other diseases must be excluded, such as meningococcemia, Rocky Mountain spotted fever, or bacteremia. Toxic shock syndrome has also been reported to be caused by strains of coagulase-negative staphylococci that produce TSST-1.[37] In such cases, coagulase-negative staphylococci that produce this toxin were isolated from the vagina and no coagulase-positive staphylococci were recovered.

8.1.14. Peritonitis. Chronic ambulatory peritoneal dialysis is an attractive alternative to hemodialysis for patients with chronic renal failure. One complication, however, is the development of peritonitis. Coagulase-negative staphylococci are the predominant causative agents although their relative rates are decreasing.[185,186] Because the number of organisms in the peritoneum may be small, inoculation of larger volumes of peritoneal fluid and filtration of large volumes of fluid followed by culture of the filter have been tried to enhance the likelihood of diagnosis. Treatment of these infections is generally successful without catheter removal, either with systemic therapy or with intraperitoneal administration of antibiotics.[187]

8.1.15. Urinary Tract Infection. Although not commonly thought of as a urinary tract pathogen, coagulase-negative staphylococcus (*S. saprophyticus*) is the second-most common cause of acute urinary tract infections in young women.[188] The organism is cultured infrequently from the genitourinary tract of young women, but there is a high correlation between colonization and subsequent development of urinary tract infection. Identification of the organism is facilitated in the clinical microbiology laboratory because of its resistance to novobiocin. The organism causes both upper and lower urinary tract disease, and the signs, symptoms, and examination of the urine of women infected with this organism are indistinguishable from those of patients infected with gram-negative enteric organisms. Other coagulase-negative staphylococci do not generally infect the urine, but do account for some infections in older patients who are usually hospitalized and have underlying urinary tract complications (e.g., indwelling urinary catheter, recent urinary surgery, bladder dysfunction, or obstruction).[189] These latter infections with coagulase-negative staphylococci account for less than 5% of all episodes of significant bacteriuria in hospitalized patients. The isolation of *S. aureus* from the urine occurs almost exclusively as a complication of *S. aureus* bacteremia and hematogenous spread to the kidney rather than as an ascending urinary tract infection.

8.1.16. CSF Shunt Infection. The most common organism causing infection of CSF shunts is coagulase-negative staphylococcus. In one series, close to 50% of the infections were caused by *S. epidermidis*.[190] The diagnosis often depends on the type of the shunt; patients with ventriculoatrial shunts usually have bacteremia, while those with ventriculoperitoneal shunts most often have peritonitis. The signs and symptoms may be only low-grade fever and shunt malfunction. Examination of the spinal fluid is important, but pleocytosis is usually mild. In general, shunt removal is required to cure infection.

8.1.17. Pyomyositis. *S. aureus* can infect a single muscle or less commonly several muscles in healthy young men or boys in tropical climates. Cases have been reported from temperate climates; infection with human immunodeficiency virus is a major risk factor.[191] Fever, muscle pain and swelling, and leukocytosis are common. Bacteremia can occur. Drainage and antibiotic therapy are usually effective.[192]

8.1.18. Meningitis. In published studies, approximately 1–9% of bacterial meningitis is caused by *S. aureus*.[193] Meningitis due to *S. aureus* occurs as a consequence of a neurosurgical procedure or as a hematogenous complication of an overwhelming, disseminated infection such as bacteremia or endocarditis.[194] Mortality in postoperative meningitis is 18%, but exceeds 50% in hematogenous infection.

8.2. Diagnosis

Because of the multiplicity of manifestations, there are no pathognomonic features that allow one to establish a diagnosis of staphylococcal infection immediately. There are, however, certain epidemiological, clinical, and laboratory features that help to establish the diagnosis or to raise suspicion. Outbreaks of nursery infections or postoperative surgical wound infections generally are caused by staphylococci; recovery of the causative organism and identification of an individual who may be responsible for shedding

the organism should be considered promptly. Heroin addicts appear particularly prone to staphylococcal infections and this organism should be considered when such patients present with fever. Other groups of patients such as diabetics, patients with hematologic malignancies, and patients with granulocytopenia appear particularly prone to staphylococcal infections. Skin manifestations of the scalded-skin syndrome may be sufficient to establish a diagnosis of staphylococcal infection. Ultimately, however, with rare exceptions, the definitive diagnosis of staphylococcal infection depends on isolating the organism for visualizing it by Gram stain from pus or other body tissues and fluids.

Epidemiological studies in the past have used phage typing of *S. aureus*. Newer studies have used molecular techniques such as restriction endonuclease analysis of plasmid DNA,[195] pulsed-field gel electrophoresis of DNA,[196] and polymerase chain reaction amplification of select DNA sequences,[197] all with promising results. In addition, there are typing systems for coagulase-negative staphylococci.[29]

9. Control and Prevention

Most *S. aureus* infections occurring in healthy persons living in the community are sporadic events that are caused by organisms carried in the nares and on the skin. Although good hygiene and proper care of minor wounds may reduce the incidence of such infections, more extensive control efforts are unlikely to be of benefit. Immunocompetent persons with recurrent staphylococcal skin infections are likely to be chronic nasal carriers, and multiple family members may be colonized. Eradication of the carrier state with agents such as intranasal mupirocin or intranasal mupirocin may decrease the frequency of infection. Patients receiving hemodialysis or peritoneal dialysis who are nasal carriers of *S. aureus* are at increased risk for serious staphylococcal infections. Elimination of the carrier state reduces the risk of infection.[62,198]

Within hospitals and nursing homes, patients colonized or infected with *S. aureus* are the major source of the organism. Chronically colonized health care workers may occasionally be the source of epidemics of staphylococcal infection. More importantly, health care workers spread staphylococci from patient to patient by transient hand carriage. Use of gloves when handling potentially infectious materials and proper handwashing between patient contacts are essential to minimize transmission between patients. More stringent isolation procedures are indicated for patients with active lesions, extensive wounds or burns, or respiratory tract infections. MRSA has been particularly difficult to control in many hospitals. Laboratory-based surveillance for MRSA permits identification of colonized and infected patients so that appropriate isolation measures may be instituted.[46,96]

Attention to details of patient care such as meticulous surgical technique, proper care of vascular catheters, and avoidance of unnecessary antibiotics can reduce the incidence of staphylococcal infection. Administration of prophylactic antibiotics immediately before surgical procedures is justified in procedures in which the risk of infection is high or the consequences of infection are severe.[200]

Treatment of staphylococcal infection with β-lactam antibiotics or vancomycin often fails to eliminate the carrier state. Asymptomatic carriers may continue to serve as reservoirs of the organism. Eradication of MRSA carriage has proved to be problematic as MRSA strains are often resistant to multiple antimicrobial agents and often become resistant to drugs used to eradicate carriage. A variety of topical and systemic agents, including mupirocin, rifampin, trimethoprim sulfamethoxazole, ciprofloxacin, novobiocin, and minocycline, have been used alone and in combination with variable results, and emergence of resistance to the agent or agents has been a recurring problem.[201] A vaccine directed against *S. aureus* capsular polysaccharide has shown short-term efficacy in hemodialysis patients.[202] The possible role of such an approach in the prevention of MRSA infection is not known.

The optimal approach to control of infection with coagulase-negative staphylococci is uncertain. The skin is heavily colonized with these organisms and patients often acquire multiple antibiotic-resistant strains after admission to the hospital.[203] Infection results when normal defenses are disrupted by such medical interventions as surgery, implantation of foreign bodies, and cytotoxic chemotherapy. Innovative approaches to prevent the attachment of staphylococci to the implanted cuff attached to central venous catheters significantly decreases catheter-related infection.[204] New technologic advances in prostheses implantation such as antibiotic beads or antibiotic-impregnated cement spacers are promising and seem to decrease the rates of postoperative infections.[205]

10. Unresolved Problems

Despite many years of intensive work toward control of *S. aureus*, there are numerous areas for continued investigation. Factors related to the host or organism itself, which make for chronic as opposed to transient carriage, remain undefined. We still do not know the rates of endogenous infection among transient compared with persistent carriers outside the hospital setting. Studies of well-defined popula-

tions are needed to assess whether sex differences exist for rates of *S. aureus* disease. With new ways to treat formerly fatal diseases, we need ongoing studies to define additional populations at high risk for serious *S. aureus* disease.

Our understanding of natural and acquired immunity to *S. aureus* is sorely lacking when compared to our understanding of other bacterial pathogens. What is lacking in the "normal" child that allows for disseminated *S. aureus* infection? Conversely, in the "normal adult," why is disseminated disease so infrequent? If mortality from *S. aureus* is to be reduced in the high-risk population already defined, more studies are needed to determine vaccine efficacy in these patients.

Perhaps the most pressing problem is the emergence of *S. aureus* isolates with intermediate and high-level resistance to glycopeptides (1, 2). Different mechanisms account for the two types of resistance. Vancomycin-intermediate *S. aureus* (VISA) harbor mutations that result in thickening of the peptidoglycan layer (3, 4). Such resistance might be overcome with high doses of vancomycin. On the other hand, vancomycin-resistant *S. aureus* (VRSA) have acquired the VanA resistance gene from enterococcal species and therefore do no exhibit a dose-dependent resistance to vancomycin (1, 5). Although vancomycin resistance rates are still low, the emergence of such strains might be inevitable, especially with the persistent intense glycopeptide use. Resistance to newer anti-staphylococcal agents like daptomycin has already been reported.

A major problem with *S. epidermidis* is determining whether the organism, when isolated from blood, is a true pathogen or a contaminant. If one looks at all patients in hospitals, only about 5–10% of individuals having one or more blood cultures positive for coagulase-negative staphylococci have a "true" clinically significant episode of bacteremia.(211) In contrast, in patients who are immunocompromised or have malignancies with indwelling intravenous catheters, the likelihood that a blood culture growing *S. epidermidis* represents significant clinical infection is substantially higher. The availability of sensitive, specific, inexpensive, and easily performed typing systems for coagulase-negative staphylococci could be of help to the clinical microbiology laboratory, to clinicians, and to infection control personnel trying to contain the spread of nosocomial infection caused by these organisms.

A second major problem with *S. epidermidis* is determining optimal antimicrobial therapy. Many of these organisms are resistant to multiple different antibiotics, and often the clinician is left with only vancomycin to use as treatment. The precise role of the addition of rifampin is not clear, and further controlled studies are needed to determine whether addition of this agent truly improves the outcome of infection with *S. epidermidis*.

Streptococcal Infections

Barry M. Gray and Dennis L. Stevens

1. Introduction

The streptococci are a large heterogeneous group of gram-positive spherically shaped bacteria widely distributed in nature. They include some of the most important agents of human disease as well as members of the normal human flora. Some streptococci have been associated mainly with disease in animals, while others have been domesticated and used for the culture of buttermilk, yogurt, and certain cheeses. Those known to cause human disease comprise two broad categories: First are the pyogenic streptococci, including the familiar β-hemolytic streptococci and the pneumococcus. These organisms are not generally part of the normal flora but cause acute, often severe, infections in normal hosts. Second are the more diverse enteric and oral streptococci, which are nearly always part of the normal flora and which are more frequently associated with opportunistic infections.

Measured in terms of mortality, morbidity, and economic costs, five streptococcal species are of major importance in human disease. (1) The group A *Streptococcus*, *Streptococcus pyogenes,* produces a wide range of infections, from pharyngitis and impetigo to puerperal sepsis, erysipelas, necrotizing fasciitis, and toxic shock syndrome. Their nonsuppurative sequelae include acute rheumatic fever and acute glomerulonephritis. (2) The group B *Streptococcus*, *Streptococcus agalactiae,* is currently a leading cause of sepsis in newborn infants and a frequent cause of postpartum infections in mothers. (3) The pneumococcus, *Streptococcus pneumoniae,* remains the most frequent cause of bacterial pneumonia in all age groups and is a common agent in otitis media, bacteremia, and meningitis. A detailed account of the pneumococcus may be found in Chapter 29. (4) Among the oral streptococci, *Streptococcus mutans* is important as a principal agent of dental caries. (5) The *Enterococcus* is part of the normal bowel flora and has been increasingly isolated as an opportunistic invader, especially in nosocomial infections. *Enterococcus* is now a separate genus but will be considered an honorary *Streptococcus* in this chapter because of its similarities to enteric streptococci.

2. Historical Background

Streptococcal infections were recognized by Greek physicians by the third century BC. A description of erysipelas is recorded in *Epidemicus* and attributed to Hippocrates. In the Middle Ages, scarlet fever, or "scarlatina," as it was called in Italy, was an eye-catching and notable disease. Sydenham's description in 1676 clearly differentiated this disease from measles and other rashes, but it was not until 1924 that G.F. and G.H. Dick showed conclusively that streptococci were the causative agents. Until the advent of penicillin, childbed fever, or puerperal sepsis, remained one of the most frequent causes of death among otherwise healthy young women. The classic works of Holmes, in 1858, and Semmelweiss, in 1861, described the transmission of this disease and provided guidelines for effective infection control and preventive measures that are still applicable today. Rheumatic fever was first described by Wells in 1812, and Bouillaud described the association of acute rheumatism and heart disease in 1835. In 1836, Bright published his account of "renal disease accompanied with secretion of albuminous urine."[1] Osler provided detailed descriptions of "malignant scarlet fever," which remained common until the advent of antibiotics (see Figure 1). Severe invasive diseases, including necrotizing fasciitis, "hemolytic streptococcus gangrene," and myositis were much less common and did not appear in the medical literature until the second and third decades of this century. During the mid-1970s to 1980s,

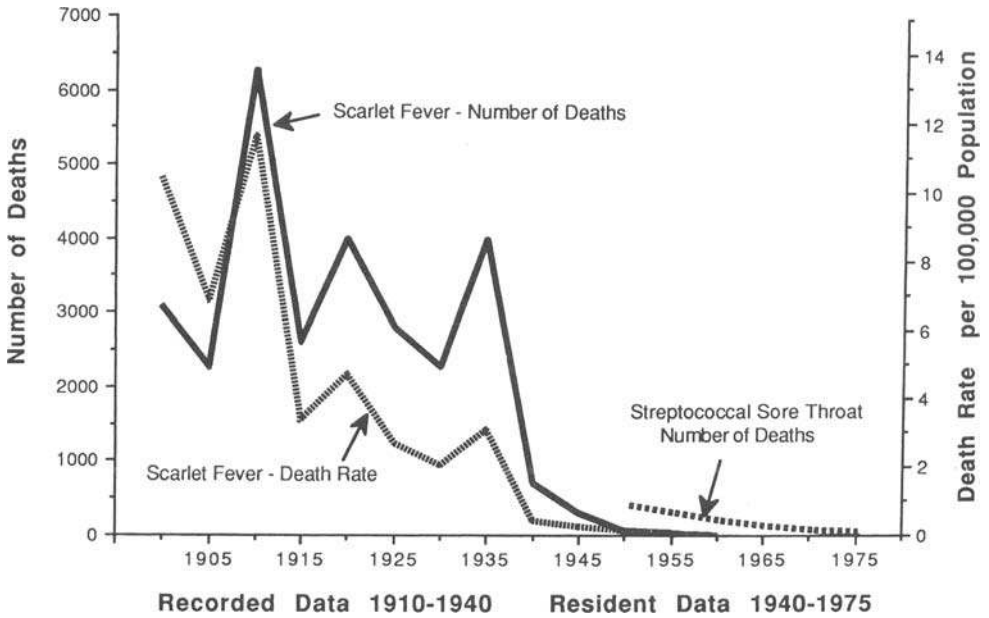

Figure 1. The number of deaths (*left-hand scale*) from scarlet fever (1900–1960) and from all streptococcal sore throat (1950–1975), with death rates (*right-hand scale*) per 100,000 population in the United States. Appropriate comparability ratios were applied beginning in 1940, and recorded data compiled according to the geographic locale where the event occurred without regard to residence (1900–1940); resident data were compiled according to the usual place of residence without regard to locale where the event occurred (1940–1975). The population used for determining rates was that of the registration area. Data were not available for streptococcal sore throat for 1900–1950. The number of states reporting for 1900–1905 was 10, gradually increasing to 48 in 1935 and to 50 states in 1960. After 1975, reporting was optional, and no accurate data are available. Sources of data: US Bureau of the Census,[234] National Office of Vital Statistics,[235] Centers for Disease Control.[236] Figure redrawn from Quinn.[1]

cases of acute rheumatic fever and acute glomerulonephritis became exceedingly rare (see Figure 2), and streptococcal disease seemed to become only an inconvenience. By the late 1980s, however, rheumatic fever made dramatic reappearance at military posts and in Utah and other areas of the United States.[2,3] There was also a dramatic increase in severe invasive infections and the emergence of a streptococcal toxic shock syndrome.[4] Group A streptococci made the headlines in the popular press as "Killer Strep," the "flesh-eating bacteria."

In the late 19th century, manyinvestigators contributed to the understanding of streptococci and their relation to human disease. By the 1880s many species had been given names such as *Streptococcus epidemicus, Streptococcus erysipelatus, Streptococcus scarlatinae,* and *Streptococcus rheumaticus,* which reflected different manifestations of streptococcal infection. The name *S. pyogenes* dates from this period but is probably of less descriptive value than the term "*Streptococcus haemolyticus,*" which was commonly used through the early part of this century. The formal classification of streptococci began when blood agar came into use and the hemolytic properties of various organisms were noted. In 1919, Brown used the term "beta" to describe streptococci that produced a 2- to 4-mm zone of clear hemolysis around colonies grown on blood agar. "Alpha" streptococci were those producing incomplete, greenish, hemolysis. Most of the isolates from severe human disease were β-hemolytic. It was not until 1928, when Lancefield introduced methods of serotyping streptococci based on immunologic reactions with cellular components, that groups and types within groups could be clearly distinguished. The group antigens were eventually shown to be specific cell wall carbohydrates. The group A streptococci were further differentiated by the M and T protein antigens. The β-hemolytic streptococci from most human infections proved to be those of group A. Armed with these new epidemiologic tools, Lancefield and Hare investigated cases of puerperal sepsis at Queen Charlotte's Hospital in London, beginning in the early 1930s.[5] Of 46 cases of postpartum sepsis, all but oneisolate was group A, and the exception was identified as the prototype of a new serologic group, designated group G. A year earlier, Hare and Colebrook observed that hemolytic streptococci resembling those associated with sepsis were never found in vaginal cultures of healthy women, but that some women carried streptococci that resembled those isolated in bovine mastitis. The latter organisms proved to be members of *Streptococcus* group B.[5]

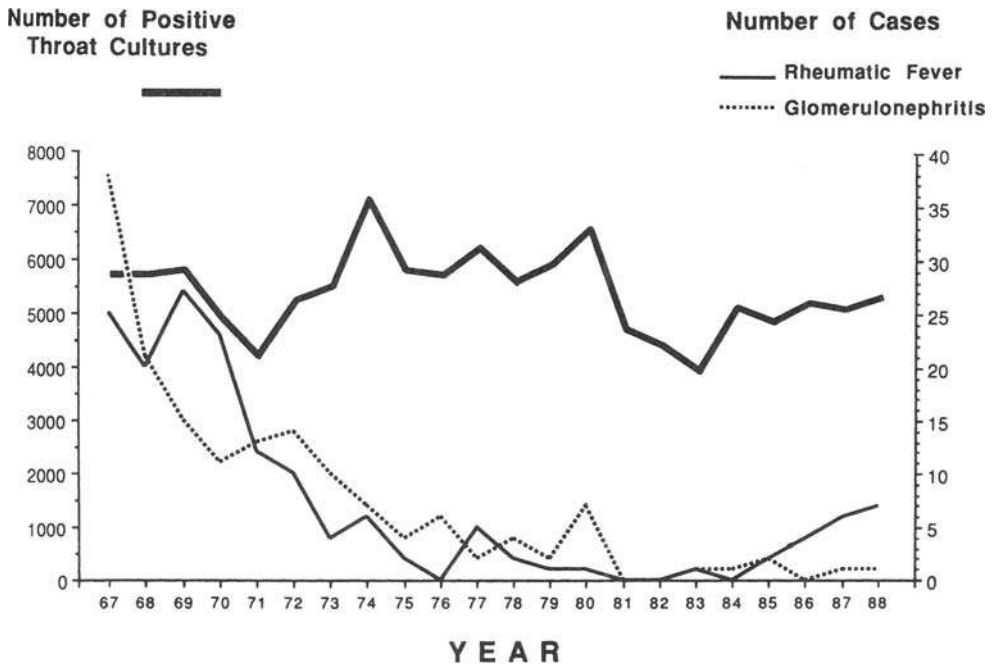

Figure 2. The number of positive throat cultures (*left-hand scale*) and number of confirmed cases of rheumatic fever and acute glomerulonephritis (*right-hand scale*) seen in private pediatric practices participating in streptococcal surveillance studies in Rochester, New York, 1967–1988. The data were kindly provided by Caroline Breese Hall, University of Rochester.

By the late 1930s the group B streptococci were recognized as important, if occasional, pathogens causing postpartum sepsis, amnionitis, endocarditis, and septic abortion. The advent of antibiotics, along with better methods for preventing nosocomial spread, resulted in a dramatic decline in streptococcal infections on obstetrical services. At Queen Charlotte's Hospital there were very few maternal deaths due to either group A or group B streptococci from 1940 to the mid-1960s. In this same period there were few cases of neonatal sepsis or meningitis attributed to streptococci of any kind in large series published in the pediatric literature. It appears unlikely that group B streptococci went simply unrecognized as perinatal pathogens for over 20 years. Rather, there seems to have been a real increase in group B disease, beginning in the United States and Europe during the 1960s. By the mid-1970s, numerous reports of group B disease appeared in the literature, and the group B *Streptococcus* was said to have come of age.

The pneumococcus has an interesting and important history, beginning with its association with pneumonia in the 1880s and later with developments in immunology, antibiotics, and the discovery of DNA.[6]

The history of *S. mutans* began in 1924, when Clark first isolated the organism from human dental caries. It was another four decades, however, before Keyes established the "infectious and transmissible nature" of dental caries in animal models and later in human subjects.[7–9] Since dental caries are chronic rather than acute infections and are not directly life-threatening, the global significance of *S. mutans* has only recently been appreciated. Dental caries, a complex but diagnosable and treatable infection, is perhaps the most common bacterial infection in humans.

Streptococcus suis is an emerging zoonotic microbe contracted by humans having direct contact with pigs and pork products. The first human infections were reported in a series of meningitis cases beginning in 1968.[10] Over the past decade several large outbreaks and over 400 human cases have been reported mainly from Asia and Europe.[11]

The enterococci, as they were called by Thiercelin in 1899, were noted as a major aerobic component of feces. Extremely hardy, they grow in bile, at high or low temperatures, in salt, and at high pH. Although for many years grouped with the streptococci because of morphologic similarities, they were transferred to the genus *Enterococcus* in 1984 on the basis of genetic studies. These and several new *Enterococcus* species were clearly distinct from the "nonenterococcal" group D streptococci, *Streptococcus bovis* and *Streptococcus equinus.* Enterococci have long been known as an occasional cause of opportunistic infections, but in the early 1970s they began to appear with increasing frequency in reports of urinary tract infection, bacteremia, and

pelvic, wound, and surgical infections. Vancomycin-resistant enterococci (VRE) are now among the most common organisms causing nosocomial infections and are difficult to eradicate because of resistance to an increasing number of antibiotics.[12]

3. Methodology

3.1. Sources of Mortality Data

Until the last decade there have been few reliable sources of mortality data for any of the streptococcal diseases. Cause-of-death coding classifications have been revised about every decade, usually without sufficient details regarding a particular etiologic agent. For example, patients may die of heart failure without rheumatic heart disease being specified; puerperal sepsis may be due to group A or group B streptococci as well as other organisms; pneumococcal pneumonia deaths are frequently counted with those attributed to influenza virus.

3.2. Sources of Morbidity Data

The most reliable data on morbidity from streptococcal diseases focus on severe invasive infections from national and regional survey areas in the United States, Canada, Europe, and Australia. The Centers for Disease Control and Prevention (CDC) began a passive nationwide surveillance for invasive group A streptococcal infections in 1993. This was expanded to include 10 large metropolitan and regional areas (about 30 million persons or 10% of the US population) as part of the Active Bacterial Core surveillance (ABCs) program of the Emerging Infections Programs Network.[13] Surveillance of group B streptococcal disease was subsequently added.[14] The ABCs have also facilitated tracking of pneumococcal disease incidence and of drug-resistant pneumococci.[15] In Europe, until recently, an informal questionnaire system has been used to track group B streptococcal disease rates[16] and pneumococcal disease has been assessed mainly by review of published reports from individual countries and localities. These efforts have now evolved into more integrated international programs, including strep-EURO[17] and Pcn-EURO.[18] Some national public health centers publish their own more detailed surveillance data. Of particular interest are reports on invasive groups A, B, C, and G streptococcal infections in Denmark 1999–2002[19] and a 10-year survey of invasive group A streptococcal infections in the Netherlands.[20] There has been little monitoring of enterococcal infections and vancomycin-resistant enterococci except in the United States from reports of hospitals participating in the National Nosocomial Infections Surveillance System.[21]

There are few accurate data on morbidity from noninvasive streptococcal infections. Since 1971, streptococcal sore throat, scarlet fever, and acute rheumatic fever have been reported only optionally to the CDC, which now relies primarily on selected hospital and population surveys. Monitoring of recent outbreaks of rheumatic fever by the CDC has been incomplete, and no mechanism for systematic nationwide reporting has been adopted. The best longitudinal incidence data on rheumatic fever are from Denmark, where meticulous records have been kept for over a 100 years.[22] The global burden of severe disease, including acute rheumatic fever, rheumatic heart disease, acute glomerulonephritis, and invasive disease is at least 18 million cases, with about 1.8 million new cases per year.[23]

3.3. Surveys

A considerable number of surveys have been published on diseases caused by various streptococcal species. The most informative have been prospective epidemiologic studies, certain family studies, and surveys of defined populations. These will be reviewed in the description of epidemiologic features of specific diseases in Section 5.1.

3.4. Laboratory Diagnosis

The major streptococcal species associated with human disease are listed in Tables 1 and 2, along with selected biological and clinical features. Our grouping of species is more for convenience than for taxonomic purposes, and various bacteriology textbooks will have different schemes, as well as more detailed information on laboratory methods. Recent changes in taxonomy and nomenclature have been reviewed by Facklam[24] and Kohler.[25] The laboratory procedures and the particular approach to identification will of course depend upon whether isolation is for clinical or research purposes and the degree of specificity required.

3.4.1. Isolation and Identification.

3.4.1.1. Media and Growth Conditions. Most streptococci grow poorly on ordinary nutrient media but grow quite well on media enriched with blood, brain, or heart infusion, serum, or glucose. Todd–Hewitt broth is an enriched buffered medium that has become a standard liquid medium for most streptococci. In the United States most laboratories use 5% sheep blood agar, whereas in Britain horse blood is generally used. Both give good hemolysis, although with sheep blood it may be necessary to "stab" the agar in the area of inoculation to ensure subsurface growth for the action of oxygen-sensitive hemolysins. While most streptococci grow well in a

Table 1. The Major Species of Pyogenic Streptococci Causing Disease in Humans

	Species designation	Lancefield group	Hemolysis	Presumptive identification	Definitive identification	Ecological niche	Normal flora	Association with disease
Group A. streptococci	*S. pyogenes*	A	β	Bacitracin sensitivity, latex agglutination, and other antigen detection methods	M proteins T proteins Opacity factor Molecular methods	Oropharynx	No (modest carrier rates)	Pharyngitis, impetigo, erysipelas, bacteremia
Group B streptococci	*S. agalactiae*	B	β	CAMP test positive	Capsular polysaccharides	Lower bowel, genital tract	High carrier rate in normal population	Neonatal sepsis, meningitis, postpartum infections, endocarditis, cellulitis
Group C streptococci	*S. equisimilis*	C	β	"Not A or B"	c-Protein DNA fingerprint DNA fingerprint	(Swine, humans)	Occasional	Pharyngitis, bacteremia, wound infections, cellulitis, often veterinary related
	S. zooepidemicus	C	β	Latex agglutination	Bacteriophage	(Horses, cattle, other animals)	No	
	S. equi	C	β				No	
Group G streptococci	"Large-colony" group G	G	β	"Not A or B" Latex agglutination	Some with M-12 protein	Pharynx, bowel	Occasional	Pharyngitis, cellulitis, bacteremia
Pneumococci	*S. pneumoniae*	None (has pneumococcal C-polysaccharide)	α	Optochin sensitive, bile soluble	Capsular polysaccharides Surface protein Molecular methods	Nasopharynx	High carrier rate in normal population	Lobar pneumonia, otitis media, bacteremia meningitis

Table 2. The Major Species of Oral and Enteric Streptococci and Enterococci Causing Disease in Humans

	Species name	Lancefield group	Hemolysis	Presumptive identification	Definitive identification	Ecological niche	Normal flora	Association with disease
Dental/oral and "Viridans" streptococci	*S. mutans*	None, E	None	—	Cell wall carbohydrate DNA hybridization	Tooth surface, dental plaque	Yes	Dental caries, endocarditis
	S. sanguis	None, H	α, β, none	—	Biochemical	Dental plaque	Yes	Endocarditis, brain abscesses, bacteremia
	S. mitis	None, O, K, M	α, β, none	—	Biochemical	Oral cavity	Yes	
	S. salivarius	None, K	None	—	Biochemical	Tongue	Yes	Bacteremia
	S. sobrinus		α, none	—	Biochemical	Oral cavity	Yes	Bacteremia
	S. oralis		α, none	—	Biochemical	Oral cavity	Yes	Bacteremia
S. anginosis group ("Milleri")	Minute colony	A, C, F, G, none	α, β, none	—	Biochemical	Oral cavity	Yes	Endocarditis, dental abscesses, brain abscesses, liver abscesses
	S. anginosis	C	β	—	Biochemical	Oral cavity	Yes	
	S. costellatus			—	Biochemical	Oral cavity	Yes	
	S. intermedius			—	Biochemical	Oral cavity	Yes	
Nutritionally deficient streptococci	*S. mitis* (mutant)	Various	α, β, none	Require pyridoxal	Biochemical	Oral cavity	Yes	Endocarditis
	S. sanguis (mutant)	Various	α, β, none	Require pyridoxal	Biochemical	Oral cavity	Yes	Endocarditis
	S. salivarius (mutant)	Various	α, none	Require pyridoxal	Biochemical	Oral cavity	Yes	Endocarditis
Microaerophilic and anaerobic streptococci	*Peptostreptococcus* (five species)	Some D	None	—	Biochemical	Oral cavity, bowel	Yes	Abscesses, otitis media, pelvic inflammatory disease
Nonenterococcal group D	*S. bovis*	D	α	—	Biochemical	Bowel	Yes	Bacteremia, endocarditis, opportunistic infections
	S. equinus	D	α	—	Biochemical	Bowel	Yes	
Enterococci (>20 species)	*E. faecalis*	D	None, β	Growth in bile-esculin 6.5% NaCl	Biochemical	Bowel	Yes	Urinary tract and surgical infections, bacteremia, endocarditis, wounds, opportunistic infections
	E. faecium	D	α, β, none		Biochemical	Bowel	Yes	

normal atmosphere, some species, particularly the "*Streptococcus milleri*" group and the peptostreptococci, do not show good growth or hemolysis without a reduced oxygen atmosphere. Pneumococci prefer to grow in 5% CO_2 or in a candle jar. Most streptococci grow best at 35–37°C, although the enterococci will also grow at 10 and 45°C.

Routine isolation of group A streptococci from throat cultures is adequately accomplished using plain sheep blood agar incubated in air at 37°C; cultures read as negative at 18–24 h should be incubated an additional 24 h for optimal sensitivity. Alternatively, throat cultures may be incubated anaerobically, although this may increase the recovery of nongroup A β-hemolytic streptococci. Selective media containing trimethoprim–sulfamethoxazole have also been evaluated and recommended for use in throat cultures.

Many laboratories now process vaginal or anorectal cultures to determine colonization by group B streptococci in pregnant women during the third trimester. A selective broth medium is generally required to minimize overgrowth of other organisms. A Todd–Hewitt broth containing nalidixic acid, polymyxin, and crystal violet has been used in large epidemiologic studies.[26,27] A similar medium is available with colistin plus nalidixic acid but without crystal violet ("Lim" broth).[28] A broth containing gentamicin plus nalidixic acid has also been widely used, although some group B strains may be inhibited by the gentamicin. A satisfactory commercial solid medium is Columbia CNA agar, which contains colistin and nalidixic acid. New Granada medium has the advantage of revealing the orange-pigmentation characteristic of group B streptococci grown in the presence of starch, but a liquid version of this medium has proved unsatisfactory.[29] For isolation of pneumococci from nasopharyngeal carriers a selective blood agar containing 4 mg/l of gentamicin sulfate, Columbia CNA agar, and plain blood agar are usually satisfactory. The enterococci grow on nearly all conventional media, including EMB (eosin–methylene blue) used for gram-negative enteric organisms.

3.4.1.2. Colony Morphology and Hemolysis. The first step in identifying a *Streptococcus* is examining colonies grown on blood agar for characteristic morphology and hemolysis. A throat culture, for example, will have much extraneous growth, but the bacteriologist will be looking for group A streptococci that have small (0.5–1 mm) opaque white colonies surrounded by a wide zone of clear β-hemolysis. Stabs made into the medium in the area of inoculation will usually clear first because the streptolysin O is more active in the absence of air. Streptolysin S, which is active on the surface, does not always produce complete hemolysis in young cultures. Occasional strains produce large (>1 mm) mucoid colonies, due to the expression of hyaluronic acid capsules (especially M type 18).

Groups A, C, and G streptococci are similar in appearance, but group B streptococci are usually larger, more mucoid, and have a narrower zone of hemolysis that is often less distinct. About 1% of wild group B strains are nonhemolytic, but this depends to some degree on the media used. Some streptococci of the *Streptococcus anginosis* ("*milleri*") group have very tiny colonies but comparatively large zones of β-hemolysis; these may include group F and the "minute colony" groups A, C, and G streptococci.[24] The α-hemolytic streptococci are quite heterogeneous and are difficult to distinguish even to the practiced eye. The pneumococci, however, are usually smooth and glossy with central craters formed by autolysis as the colonies grow beyond 18–24 h. Colonies of type 3 pneumococci are often very large and have a distinctive mucoid appearance. Enterococci have rather buttery colonies, compared to most of the streptococci, and usually produce no hemolysis or may be β-hemolytic on horse blood and α-hemolytic on sheep blood.

3.4.1.3. Presumptive Identification. For practical purposes, group A streptococci can be identified presumptively by the bacitracin sensitivity test of Maxted in which a 0.04-unit bacitracin (TAXO^R) disk is placed on a pure subculture of a β-hemolytic *Streptococcus*. Group A streptococci are extremely sensitive and uniformly show a zone of inhibition, whereas only 5–10% of group C or G strains may give a false-positive result. The simplest of several tests for group B streptococci is the CAMP test (described by Christie, Atkins, and Munch-Petersen in 1944). The test is performed by inoculating a streak of the group B streptococcus perpendicular to a streak of *S. aureus* on a sheep blood agar plate; an arrowhead-shaped area of complete hemolysis indicates the presence of CAMP factor, which enhances the effect of the staphylococcal β lysin. Streptococci reported simply as "not A or B" on the basis of presumptive tests usually prove to be group C or G. Pneumococci are distinguished from other α-hemolytic streptococci by sensitivity to optochin in a manner similar to that of the bacitracin test for group A streptococci. In addition, the bile solubility test of Neufeld remains useful for separating pneumococci from the occasional optochin-sensitive viridans *Streptococcus*. Enterococci are identified by growth on bile-esculin media and in 6.5% NaCl. Further identification of these and the viridans streptococci is done with various panels of biochemical tests.

3.4.1.4. Rapid Antigen Detection Tests (RADT). A number of direct antigen detection tests are currently in use for diagnosis of streptococcal pharyngitis. These RADTs yield results in 10–60 min and permit the physician to appropriately treat streptococcal pharyngitis without the delay of conventional cultures. Older latex or particle agglutination tests have good specificity but poor sensitivity.

Most newer methods are based upon the extraction of cell wall antigens from throat swabs followed by their detection by enzyme immunoassay (EIA). In general, these tests have excellent specificity (>95%), but the sensitivity is on the order of 80–90%, or even lower, compared to culture. Some optical immunoassays and chemiluminescent DNA probe tests may approach the accuracy of culture. However, there are conflicting results among studies and few that directly compare various methods. For this reason it is recommended that a throat culture be done when the rapid test is negative. Individual laboratories should verify their own test parameters to assess the need for back-up cultures and minimize the risk of false-negative results.[30]

Two problems continue to limit the usefulness of the RSDTs. One is that they detect only group A streptococci, whereas acute pharyngitis is sometimes caused by group C or G streptococci, and these may require antibiotic therapy. The other is cost: A blood agar plate currently costs about $0.25, whereas EIA tests cost about $2.00 each, and optical immunoassays cost somewhat more. Although some RADTs may be waived as "simple" laboratory tests, this may not exempt the physicians laboratory from compliance or certification under the US Federal regulations adopted in the Clinical Laboratory Improvement Act (CLIA).

Particle agglutination methodologies have been employed for detecting group B streptococcal antigens in CSF or urine. Testing of urine samples has been discouraged because the urine sample may be positive as the result of skin or genitourinary contamination, or possibly from intestinal absorption and urinary excretion of antigen.[31] Many laboratories have discontinued antigen testing of CSF because it generally offers no better sensitivity than a properly performed Gram stain. No rapid tests have proved sensitive enough to determine maternal colonization directly from vaginal swabs. However, sensitive PCR test is now coming into use.[32]

3.4.1.5. Definitive Identification. Streptococci are classified into Lancefield groups on the basis of their cell wall carbohydrate antigens. The classical methods of grouping employ an extraction step, usually hot acid (Lancefield method) or nitrous acid, followed by detection of liberated antigens with specific rabbit antisera. More recently, latex and similar particle agglutination kits make it possible for any laboratory to provide rapid and accurate group identification without having to maintain serologic supplies. Molecular methods are now replacing some of the more tedious procedures.

Classic typing of group A streptococci is done by precipitation of M and T proteins with specific antisera, as described by Lancefield in 1928.[5] The M protein is the major antigenic surface marker, and antibodies to its variable N-terminal region are protective both in humans and in mouse protection tests. The T proteins are trypsin-resistant antigens that are not associated with protection but are useful markers for certain M types and for strains having no detectable M protein. T typing is done first by agglutination after trypsinization of the streptococcal cells. M typing is then done on the basis of T typing results, after an acid extraction step and precipitation with specific antisera. For example, T1 strains are invariably M1, and T3 strains are M3, whereas T8/25/Imp.19 strains may be M2, 55, or 57. About 93 M types are internationally recognized, but a quarter or more of isolates are not typeable with either T or M antisera. The major technical difficulties with this system are the difficulty in making antisera and validating new M types by functional protection testis. Testing for many of the less common but established M types cannot be done simply because typing sera are no longer available.[33] One method to overcome these problems is a surrogate typing system based on the neutralization of opacity factor (OF) described by Fraser and Maxted in 1979 and later modified by Johnson and Kaplan.[34] This test is relatively simple and correlates well with M typing. A second surrogate for M typing is "*emm* typing," which is based on the DNA sequences of putative M protein genes, described in the next section.

The epidemiologic importance of group A typing is obvious, since certain M types are commonly associated with specific kinds of infection or sequelae. Table 3 lists the most common M types associated with uncomplicated pharyngitis, severe systemic infections, and rheumatic fever, and with acute glomerulonephritis.[35–37] Molecular studies have confirmed these observations and further identified *emm*-type patterns particularly associated with skin infection.[38] M1 strains are common in both uncomplicated pharyngitis and in severe invasive disease, but epidemiologic evidence suggests that the serious disease is caused by especially virulent strains or clones, and virulence is not always associated as a general property of that serotype.[36] Molecular methods, described below, now confirm such observations and shed light on the evolution of virulent clones and the virulence genes themselves.[39–41]

The typing of group B streptococci is based on the detection of capsular polysaccharides, listed in Table 4. There are four "classical" types: Ia, Ib, II, and III; two newly recognized types of growing importance: IV, V; three new relatively uncommon types: VI, VII, VIII; and a newly proposed type IX.[42,43] In her original description of the type polysaccharides, Lancefield noted that, finding no antigens analogous to the M proteins of group A streptococci, she was looking for capsular materials like those found in the capsules of pneumococci.[5] The group B indeed proved to have capsular polysaccharides, and are all similar in structure,

Table 3. Group A Streptococcal M Protein Serotypes Commonly Associated with Uncomplicated Pharyngitis, Scarlet Fever, Severe Systemic Infections, Acute Rheumatic Fever, and Acute Glomerulonephritis, Listed in Approximate Order of Frequency[a]

Uncomplicated pharyngitis	Scarlet fever	Severe systemic infections	Acute rheumatic fever	Acute glomerulonephritis
1	3	1	3	2
12	4	3	1	1
4	1	18	18	49
2	22	12	5	12
28	6	22	4	4
3	2	5	6	55

[a]Data from Dillon et al.,[35] Johnson et al.,[36] and Colman et al.[37] Severe infections included streptococcal toxic shock, septicemia, pneumonia or empyema, joint, and deep soft tissue infections. Note that strains associated with acute glomerulonephritis may be isolated from throat (M1 and M12) or skin sites (M55) or either throat or skin (M4, M49).

Table 4. Type-Specific Antigens and Cellular Components of Group B Streptococci

Capsular polysaccharides	Serotypes Ia, Ib, II, III, IV, V, VI, VII, VII, IX (proposed) Protects organism against phagocytosis
c Protein	Occurs with all type Ib, many type Ia (designated Ia/c), about 50% of II (II/c), and some type III strains Binds to the Fc portion of IgA
β-Hemolysin	Pore-forming cytolytic toxin involved in cell invasion and injury, also confers orange pigmentation to colonies
CAMP factor	Enhances sphyngomyelinase activity (CAMP test)
Hyaluronate lyase	Degrades hyaluronan and chondroitin sulfate in basement membranes, presumably facilitating invasion
Degradative enzymes	C5a peptidase inactivates complement-mediated chemotaxis; extracellular peptidases, nucleases, collaginases, serine protease

composed of glucose, galactose, and *N*-acetylglucosamine. Unlike pneumococci, they all have side chains containing terminal sialic acid residues that are major antigenic determinants. There are a large number of surface protein antigens of pathogenic and immunological importance.[44] Type Ib strains, about half of type II and some type III strains also carry the "c protein," a complex antigen that binds the Fc portion of IgA. The R antigens, which are resistant to trypsin, occur on some type II and III strains but are not frequent among human isolates. The X antigen is found almost exclusively in veterinary strains, particularly those from bovine mastitis.

The pneumococci are classified into about 90 distinct types based on antisera to their capsular polysaccharides. The Danish typing system recognizes 48 main types or groups of closely related types. (Each of these corresponds to an individual type of the American system, which is no longer in common use.) For example, types 1–5 each contain only one distinct type. Group 6 includes type 6A (America type 6) and type 6B (American type 26) and a recently identified type 6C.[45] Knowledge of the distribution of types in human infections led directly to the selection of the most important types in the formulation of pneumococcal vaccines.

Group D and viridans streptococci are usually speciated by their pattern of biochemical reactions. Various test kits and automated equipment are in general use in most clinical laboratories and give basically similar results. However, these products do not always conform to the latest taxonomic changes. Two major identification schemes are currently in use, one from Great Britain, the other from the CDC in the United States. They differ mainly in the classification of group F and the *S. anginosis* ("*milleri*") group. This group currently consists of three species: *S. anginosis, Streptococcus constellatus,* and *Streptococcus intermedius,* which differ in their production of β-glucosidase, hyaluronidase, and several other glycosidases.[24] A group of organisms formerly described as "nutritionally deficient streptococci" have been reclassified into two new genera, *Abiotrophia* and *Granulaticella*, on the basis of 16S ribosomal RNA similarities.[24] These organisms are noteworthy as a cause endocarditis.[46] *Streptococcus mutans* is divided into eight serologic types based on cell wall carbohydrates, but epidemiologic

studies now favor molecular methods for distinguishing strains among types.[8]

Most enterococci share a glycerol teichoic acid antigen with the group D streptococci. However, enterococci are usually characterized by their ability to grow in broth containing 6.5% NaCl and hydrolyze esculin in the presence of 40% bile salts (bile-esculin medium), and a positive PYR reaction. Strains are divided into five major groups and 33 species mainly on the basis of biochemical tests. *Enterococcus faecalis* is distinguished from *Enterococcus faecium* by growth in the presence of tellurite, reduction of tetrazolium, and fermentation of sorbitol.[25,47]

3.4.1.6. Molecular Methods. Molecular methods have now been applied to various streptococcal species for direct detection, identification, epidemiology, and studies of molecular evolution. Although it is unlikely that the polymerase chain reaction (PCR) will ever completely replace the blood agar plate, hybridization with labeled gene probes has been successfully employed for detection of group A streptococci from throat swabs of patients with pharyngitis.[48] A rapid PCR test has been developed for detection of group B streptococcal colonization directly from swabs in pregnant women.[32] Pneumococcal DNA in materials such as blood cultures and middle ear fluids has also been demonstrated by PCR, using primers derived from known nucleotide sequences from genes coding for autolysin or pneumolysin.[49]

Molecular identification of group A streptococci M protein genes, called *emm* typing, has now essentially replaced classical serologic M typing.[50,51] This method is based on DNA sequencing of the N-terminal end of the gene, which codes for the highly variable antigenic portion of the M protein generally detected by specific antisera. In addition to the 93 classically validated M types, 110 officially designated *emm* types have been described, along with many more provision types and subtypes. The CDC maintains a dedicated, curated web site and searchable database of validated *emm* types, provisional types, and subtypes (http://www.cdc.gov/ncidod/biotech/strep/strepindex.htm). This has been especially useful for epidemiological tracking of otherwise nontypeable strains. It also has the advantage that *emm* types can be identified in isolates that express only small amounts of M protein and are only weakly antigenic in conventional M typing.[33] Nevertheless, the *emm* typing is not without its own set of difficulties. Many strains have several *emm* or M protein-like genes that may look like M protein genes but code for proteins with lectin-like functions, such as binding of immunoglobulins or fibronectin, and some appear to be extra copies or even defective genes. The amplification and/or detection of these genes may depend greatly upon the selection of primers and the conditions of the assay.

Several other molecular approaches differentiate among streptococcal strains or types but are not necessarily intended to correlate with given M or T typing systems. "Ribotyping" is based on the pattern of amplified ribosomal RNA in agarose gel electrophoresis or by automated systems. Depending upon the primers utilized, species-specific and sometimes strain-specific identification may be possible. Because ribosomal RNA nucleotide sequences are highly conserved, few differences may be seen even between strains of differing M types.[52] Restriction fragment length polymorphism (RFLP) relies upon endonucleases, such as *Sma*I or *Sfi*I, that cut DNA at relatively fewer sites, producing longer more distinctively sized fragments. These large (20–500 kb) fragments must be resolved using pulse field gel electrophoresis, hence the more familiar name, PFGE. PFGE has proved useful in a wide variety of epidemiological studies.[53] Various methods similar to those just described have been employed for epidemiological studies of group B[54] and group G[55] streptococci, pneumococci,[56] and enterococci.[57,58] Molecular methods have also focused on genes of particular interest because of their function in disease, antibiotic susceptibility, or epidemiology. Two highly pathogenic clones of group A *Streptococcus* were tracked and delineated by the allelic variants of their scarlet fever toxin (SPE-A), serotyping, and multilocus enzyme electrophoresis (MLEE).[59]

Two new molecular typing methods have come to the fore over the past decade: MLST—multilocus sequence typing and MLVA—multilocus variable-number tandem repeat analysis. MLST was proposed in 1998 as a universal definitive and portable method characterizing bacteria.[60] Selected internal fragments of about 500 bp in length are amplified from seven different "housekeeping" genes, which are relatively stable genetic markers. The sequence of each locus is assigned a different number, whether it represents a single point mutation or a large recombinatorial replacement. MLST methods are in use for group A *Streptococcus*,[61] group B *Streptococcus*,[62] *S. pneumoniae*,[63] *S. suis*,[64] and *E. faecium*.[65] These techniques have been used to track clonal spread of group A streptococci resistant to multiple antibiotics,[53] to characterize nontypeable group B streptococci,[66] to study the population biology of pneumococci,[67] and to assess both nosocomial[58] and global spread[57] of vancomycin-resistant enterococci.

MLVA methods depend on PCR amplification of selected gene segments that contain a variable number of short repeated sequences. These segments vary among isolates and yield gene products of different lengths that can be separated by electrophoresis on agarose gels. The banding patterns (done individually or in a multiplex) are highly reproducible and most systems have powers of resolution equal to that of MLST. MLVA is generally cheaper, much

easier to perform, but more suitable for short-term outbreak investigations than for long-term population studies, compared to MLST. In some systems each allele associated with given locus is assigned a number corresponding to the number of tandem repeats, thus giving a numerical repeat profile that can be compared without reference to the gel pattern itself.[68] MLVA methods have been applied to pneumococci,[69] *E. faecalis*,[68] and *E. faecium*.[70] However, the current MLVA typing scheme for *E. faecium* was found to be somewhat less discriminatory than MLST and PFGE for hospital studies.[71]

3.4.2. Serologic and Immunologic Diagnostic Methods. Antibody tests have been developed as clinical and epidemiologic tools in the study of group A, group B, and pneumococcal infections. In general, antibodies are markers of past experience with the organisms and do not indicate when an infection took place. For this reason they are most useful when acute and convalescent antibody levels are compared in relation to an episode of presumed infection.

Assays for the group A *Streptococcus* are based on the development of antibodies either to cellular antigens or to extracellular enzymes. These are listed in Table 5 and further described in Section 4. Tests for antibody to M proteins, which confer immunity, and to the group A carbohydrate have been used primarily for research purposes. Assays used clinically for confirmation of recent infections have been reviewed by Shet and Kaplan.[72] The antistreptolysin O (ASO) is the most reliable and is widely available. It is of no immediate value in the diagnosis of acute streptococcal pharyngitis, and it should not be expected to differentiate carriage from infection. Nevertheless, about 80% of patients with rheumatic fever or pharyngitis-associated acute glomerulonephritis infection will mount a significant ASO response. A rise in titer is usually seen 3–6 weeks after infection, and a rise, even if modest, is more helpful than a single determination. Test kits give a titer of >166 Todd units as elevated for adults, but there is considerable variation in the "normal" values among populations and laboratories. In general, single ASO titers above 250 in adults and above 300 in school-aged children are considered elevated. Compared to pharyngitis, skin infections tend to elicit feeble ASO responses but greater responses to DNase B. The anti-DNase B titer peaks later, at 6–8 weeks after either skin or throat infections. This test is often useful when the initial ASO is low or negative. There is less clinical experience with the anti-hyaluronidase and anti-streptokinase tests, although they may give comparable results and may be useful as confirmatory tests. The Streptozyme® hemagglutination test (Wampole Laboratories, Stamford, CT) is a crude screening test based on reactions with *a mixture of streptococcal antigens, including streptolysin O, DNase, NADase, streptokinase, and hyaluronidase.* It is simple and widely available but is not considered sufficiently reliable by many authorities. Positive responses appear earlier (1–2 weeks) and should always be confirmed with one or more of the standardized assays whenever rheumatic fever or acute glomerulonephritis is suspected.[30]

Table 5. Group A Streptococcal Antigens and Antibodies[a]

	Antibody	Clinical interpretation
Cellular antigens		
M protein	(M protein)	Type specific, confers immunity. Some antigens cross-reactive with sarcolemma of heart muscle
Group A carbohydrate	(Group A CHO)	Slow response following infection
Hyaluronic acid capsule	None	Not antigenic
Extracellular enzymes		
Streptolysin O	Antistreptolysin O (ASO)	Increases after most group A infections, more reliable for throat than skin infections
Deoxyribonuclease A, B, C, D	Anti-DNase B	Most useful test for skin infections, also reliable for throat infections; anti-DNase A and C inconsistent
Hyaluronidase	Antihyaluronidase	Increases after most group A infections
Streptokinase	Antistreptokinase (ASK)	Increases after most group A infections; streptokinase A more common than B
Nicotinamide adenine dinucleotidase	Anti-NADase (anti-DPNase)	Response better after throat than skin infections; common to groups A, C, and G streptococci
Proteinase	Antiproteinase	Antibodies appear in small amounts following infection with group A
Erythrogenic toxins A, B, and C	Antierythrogenic toxin	Toxin produces rash of scarlet fever; Dick skin test for immunity or susceptibility

[a] Adapted from Quinn.[1]

Assays for antibody to pneumococcal and group B streptococcal capsular polysaccharides have employed radioimmunoassay (RIA) for total antibody and enzyme-linked immunosorbent assays (ELISA) for total and class-specific antibody determinations. Since both pneumococci and group B streptococci have multiple capsular types, antibody to specific types must be considered. Although it has so far proved impossible to establish an absolute or minimal protective antibody level, infection appears to be more common in subjects with low antibody levels against the specific capsular antigen of the type causing infection. Assays for type-specific pneumococcal antibodies are now commercially available.

4. Biological Characteristics of the Organisms
